WITH EXTENSIVE IMPROVEMENTS AND ADDITIONS; AND NUMEROUS ENGRAVINGS.

VOLUME V.

ADAM AND CHARLES BLACK, EDINBURGH.

MDCCCLIV.

[The Proprietors of this Work give notice that they reserve the right of Translating it.]

Bombay. and with great expedition, by the Parsees, who are generally accounted excellent ship-carpenters. Here is a rope-walk, equal to any in England, with the single exception of the king's yard at Portsmouth, where cables and all sorts of lesser cordage are manufactured. It has also a covering to protect the workmen from the heat or inclemency of the weather. The dockyard is large and well contrived, having ample supplies of naval stores deposited in the warehouses, together with large quantities of timber for repairing and building ships, and forges for all kinds of smith-work. With these advantages Bombay claims a distinguished rank as a naval arsenal. Many merchant-ships of from 600 to 1300 tons, partly for the country trade and partly for the service of the East India Company, have been built in its docks, and, in beauty of construction, good workmanship, and durability, they have been considered superior to any other class of merchant-ships in the world. Some ships of the line, and several frigates for the British navy, have also been built at this port. Among them may be mentioned the Minden, a 74-gun ship launched in 1810; this was followed some years later by the Wellesley, also a 74-gun ship; and more recently the Meeanee of 80 guns has been added to the list. These ships were all built of Malabar teak, which is esteemed superior to any in India. The teak forests, from which supplies of wood are derived, lie along the western side of the Ghaut Mountains, and other contiguous ridges to the north and east of Bassein; the numerous streams which descend from them affording water-carriage for the timber. The docks belong to the Company. They are entirely occupied by Parsees, who are esteemed remarkably skilful and assiduous. Bombay, thus possessing, in the skill of its workmen, the excellence of its timber, and the superiority of its docks, all that is necessary for a naval arsenal, is a station of the first importance to the British power in India.

From its position, Bombay commands an extensive commerce with the countries situated in the Persian and Arabian Gulfs. It also possesses much facility of commercial intercourse with different parts of the territories subject to the other presidencies of India, and it carries on a valuable trade with Europe, America, and China. The chief articles of export are cotton, cashmere shawls, wool, opium, coffee, pepper, ivory, and gums. The principal imports are British manufactures, raw silk from China, wine, beer, and tea. The foreign trade has more than doubled within the last twenty years; and its exports alone now amount to seven millions sterling. The value (in rupees) of the imports and exports to the United Kingdom has increased thus:-

	Imports.	Exports.
1813-14	Rs. 926,980	Rs. 3,051,543
1823-24	5,571,313	5,953,859
1833-34	9,042,390	10,184,795
1843 -44	24,335,718	17,046,748
1852-53	29,319,750	29,385,955

The shipping that entered and cleared the port in 1852-53, was as follows:--

	ARRIVED.		DEPARTED.	
Square-rigged Country craft	Vessels. 522	Tonnage. 227,751 679,696	Vessels. 522 41.696	Tonnage. 215,209 693,119
•	,	0,0,000	11,000	000,110

According to the census of 1849 Bombay Island, with Colaba, contains a population of 566,119. This amount is inclusive of the military and also of the floating population of the harbour. More than one-half of the inhabitants are Hindus. The Mahometans somewhat exceed one-fifth of the entire population. Next in point of numbers are the Parsees. Many of this last-mentioned class are extensively engaged in commerce; they are the brokers and factors of Europeans, and share largely in most of the foreign speculations of European mercantile houses. They are a rich, industrious, and active body of men, who contribute greatly to the prosperity of the settlement. The Parsees are the descendants of the ancient fire-worshippers of Persia, who Bombay. took refuge in Khorassan upon the conquest of that country by the Moslems in the seventh century. Their first appearance in India occurred about the year 766, and their earliest settlement was the island of Diu, on the south coast of the peninsula of Kattywar. From thence they migrated to Surat and Broach, and finally to Bombay. The various castes into which the total population of Bombay is distributed, and the proportion comprised in each, are thus particularized:—

Jains, Lingaehs, or Boodhists	
Hindus of other castes	289,995
Mussulmans	124,155
Parsees	114,698
Jews	1,132
Native Christians	7,456
Indo-Britons	1,333
Indo-Portuguese	5,417
Pure European	5,088
Seedee, Negro, African	839
Other castes	7,118

Total, 566,119

It has been often remarked that the people of India differ from Europeans, not only in race, in language, and in creed, but also in their manners and modes of thought. A striking illustration of the truth of the observation is afforded in the organization and existence to a very recent period of the great plundering confederacy of Bombay. This partnership, Plundering composed of upwards of forty individuals, and affording em-confederployment to between two and three hundred subordinates, acy. had been established upwards of thirty years for the receipt of goods stolen from merchant-ships. The harbour was the principal scene of plunder, where the members of the gang were each day systematically distributed at the different quays, from which their boats and canoes were sent off to the loading and unloading ships. The plunder obtained was conveyed openly to the shoreas though legally acquired, and thence transported to the partnership warehouses, where each morning it was brought to auction without any attempt at concealment. The books were kept with strict regularity, and the division of profits made with scrupulous honesty; two shares being invariably reserved to be distributed in charity. This successful perpetration of offences, though practised without interruption for a series of years, had been carried on without suspicion on the part of the European officers of the government; while the silence of the natives was secured either by the respect for caste, or by resort to intimidation. It was not till the year 1843 that the system was discovered, and those concerned in it brought to justice.

The Company's naval force at Bombay, including frigates, Naval iron steamers, and other craft, consists of forty-six vessels, and force. to man this navy a regular establishment of officers and seamen is required. The western coast of India, from the shores of the Persian Gulf to Goa, was formerly infested by hordes of pirates, who were distinguished, particularly those in the northerly tracts, by courage, address, and habits of extreme ferocity. It was to protect the country trade against the depredations of these banditti, who had haunted those seas since the time of Alexander the Great, that the East India Company found it necessary to maintain an armed maritime force.

The military force of the presidency, composed of the Military regular troops of the Crown and Company, but exclusive of force. local and police corps, amounts to 41,426 men, of whom 10,244 are Europeans, and 31,182 natives. If the strength of the local and police corps be added, the aggregate will be swelled to 59,430. An augmentation of force being required, consequent upon the recent extension of the British dominions in India, another European regiment is about to be added to the infantry of this presidency.

Bombay. The principal divisions of the Bombay army are as follow:—

	European.	Native.	Total.
Presidency Garrison— Headquarters, Bombay Southern Division—	678	3,264	3,942

Education.

A board of instruction presides over the government educational establishments of this presidency. These institutions consist of two principal classes. The first comprehends all the vernacular schools in which knowledge is communicated through the medium of the native languages. Under the second are ranked the institutions in which the higher thranches of learning are taught through the medium of English. Various particulars connected with these seminaries are detailed in the following table.

	Expense.	Teachers	Pupils.

Judicial establishment. In 1827 a supreme court of justice was established at Bombay, constituted under letters-patent from the crown, under powers granted by act of parliament. It consists of a chief justice and one puisne judge, from whose decision an appeal lies to the queen in council. The modes of procedure in this court are assimilated to those of the courts at Westminster; but its jurisdiction is restricted to the city of Bombay, except in regard to British subjects.

Bombay is the seat of a bishopric, subject to the ecclesiantical jurisdiction of the bishop of Calcutta as metropolitan. The ecclesiastical establishment consists of a bishop, an Ecclesiasarchdeacon, seven chaplains, and sixteen assistant chaplains, tical estarchdeacon, seven chaplains, and sixteen assistant chaplains. There are also at this presidency two ministers of the Church blishment, of Scotland, appointed and maintained by the East India Company.

Subject to the superintendence, direction, and control of Population the governor-general of India in council, the government and extent of the territories of Bombay is vested in a governor and of presithree councillors, styled "the Governor in Council of Bom-dency. bay." The following table exhibits the details of the area and population of the several subdivisions into which the Bombay territories are distributed:—

	Area

Facilities of communication, so important to the prosperity Roads and of commerce, agriculture, and manufactures, as well as so railways. essential to social improvements, are for the most part rare in India. In the Bombay territories government has made considerable efforts to effect beneficial changes in this respect, but the difficulties are many, various, and sometimes almost insurmountable. The great expense of constructing roads of materials calculated for durability, with drains, bridges, and other appurtenances essential to their completeness, and of maintaining them in a state of efficiency, is but one among those difficulties. Another is the character of the country to be traversed; roads, in many cases connecting places of some importance, have in the intermediate space to pass through a tract of country little if at all removed from the character of a desert. A further, and in a great degree a peculiar difficulty arises from the frequent deficiency of water. The construction of roads in the hot climate of Bombay is useless unless water can be found for the consumption of the beasts of burden, and this has frequently to be provided by additional works, involving an increased outlay. If to these sources of difficulty and expense be added that arising from the rugged and mountainous character of

Bomb-Ketch Bona.

History.

a large part of the country, the feeling likely to be excited will be that of surprise that so much should have been effected. The grand obstacle, after leaving the coast, is the range of mountains known as the Western Ghauts, the principal passes in which are at present the Tull and the Bhore Ghaut, traversed by what may be termed two radical roads, connecting the port of Bombay with the interior. A railway from the city of Bombay, traversing the country in a northerly direction, and intended to effect a junction with the Calcutta and Delhi trunk line, is now under construction, and has been opened as far as Tannah. A branch line from this will connect the cotton districts of the valley of Berar with the port of shipment on the western coast; while another in a south-eastern direction, via Poonah and Bellary, is projected, to facilitate communication with Ma-

Bombay Island appears to have been first occupied by the Portuguese about the year 1530, having been previously dependent on the ruler of Guzerat. In 1661 it was ceded by the crown of Portugal in full sovereignty to Charles the Second of England, by the treaty of marriage concluded with that power when he espoused the Infanta; and shortly after it was transferred by royal grant to the East India Company. In process of time it superseded in importance the factory at Surat, and became the principal British settlement on the western coast. Aurungzebe, emperor of Delhi, invaded the island in 1688 and laid siege to the town, but was prevailed upon to withdraw his troops upon the receipt of a sum of money.

The extension of the British dominions on the western side

Bonald.

of India was both slow and subject to frequent checks. Bona Dea Previously to the year 1775 the possessions of the East India Company in this quarter of the empire were limited to the island of Bombay, the harbour of Bankote, with Port Victoria, and the factories of Ahmedabad, Broach, and Surat. In the year last-mentioned, Salsette and the adjacent islands were obtained by treaty with the Peishwa. About the same period various acquisitions were made in Guzerat, but these, after a brief occupation by their new masters, again reverted to the Mahrattas. It was not till the close of the eighteenth century that the company obtained the grant of the city and territory of Surat, nor until the commencement of the nineteenth, that the district of Broach became permanently a British possession. By the treaty of Baroda in 1805, portions of the collectorates of Ahmedabad and Kaira were ceded by the Guicowar, as were the ports of Malwan, Vingorla, and some others, by the rajahs of Kolapore and Sawunt Warree. These, however, in the aggregate constitute but a fragment of the territory now comprised within the presidency, the great bulk of which is of still more recent acquisition. One vast accession took place in 1818, upon the downfall of the Peishwa, when the possessions of that potentate were incorporated with the Company's dominions. Since that period the limits of the British empire on the side of Western India have been still further extended by the annexation of Sinde, and the transfer to the Company of the Angrias territories, and the principality of Sattara. The first of these became subject to British rule by the results of war; the latter two lapsed to the paramount power upon the failure of heirs to their last native rulers.

BOMB-KETCH. See GALLEOT.

BOMBUS (βόμβος), literally, a deep hollow sound or humming noise, such as the buzzing of bees. The word was used to denote a kind of applause with the hands in ancient auditories. (Suet. Nero, 20.) This term is also employed to designate a genus of insects, of which our common Humble Bee is the type. See Entomology.

BOMBYX, the silkworm. See Entomology.

BOMONICÆ (βωμονείκαι), the name given to those Lacedæmonian youths who contended at the altar of Artemis Orthia for the prize of endurance, by submitting their bodies to the lash. (Hyg. Fab. 261.)

BONA, GIOVANNI, a learned and pious cardinal, was born in 1609, at Mondovi in Piedmont, and died at Rome in 1674. His principal work is his Rerum Liturgicarum Lib. II., Rome, 1671, which is an authority on all that pertains to the Romish service of the mass.

Bona, a fortified town and seaport of Algiers, in the province, and 85 miles N.E. of the town, of Constantine, is situated on an open bay at the mouth of the Seybouse in Lat. 36. 54. N. Long. 7. 47. E. The town is about two miles in circumference, and is surrounded by a high wall with square turrets and four gates. It has been much improved since it came into the possession of the French, by the formation of good streets and squares, and the erection of many handsome and commodious houses. It now has bazaars, markets, coffeehouses, reading-rooms, hospitals, two Roman Catholic chapels, synagogue, mosque, theatre, barracks, and several schools; and it is the seat of a tribunal of primary instance. It is the principal seat of the coral fishery, and has a considerable trade in corn, wool, hides, and wax; and manufactures of native garments, tapestry, saddles, &c. The town and harbour are defended by a citadel, Casbah, on a hill a little to the north of the town, and surrounded by thick walls, about a quarter of a mile in circuit.

Remains of the ancient Hippo-regius, celebrated as the see of St Augustine, are to be found about a mile to the

south of the town, and consist principally of large cisterns, and part of the Roman walls. The population of Bona in 1850 amounted to 8134, of whom 5250 were Europeans.

Bona Dea, a Roman divinity, who is described as the wife, sister, or daughter of Faunus, and so famous for her chastity that after her death she was deified. Her sacrifices were performed only by women, and in so secret a manner that it was death for any man to intrude himself into the assembly. Cicero reproaches P. Clodius with having entered this temple disguised as a singing woman, and by his presence polluted the mysteries of the Bona Dea. What kind of mysteries these were, we learn incidentally from Juvenal, Sat. vi. 313, where the abominations practised in them are very significantly pointed at.

Bona Fides, in Law. When a person performs any action which he believes at the time to be just and lawful, he is said to have acted in bona fide, "in good faith."

Bona Mobilia, movable effects or goods.

Bona Notabilia are such goods as a person dying has in another diocese than that in which he dies, amounting to the value of five pounds at least; in which case the will of the deceased must be proved, or administration granted, in the court of the archbishop of the province, unless, by composition or custom, any dioceses are authorized to do it, when rated at a greater sum.

Bona Vacantia, goods, such as royal fish, shipwrecks, treasure-trove, waifs, and estrays, in which no one can claim

BONALD (Louis Gabriel Ambroise) Vicomte De, a French philosophical writer, was born in the year 1754 at Monna, near Milhau, in the department of Aveyron. He began life as a soldier, but having little sympathy with the revolutionary principles then abroad, he emigrated in 1791 and joined the army of Condé. Soon afterwards he quitted the service and retired to Heidelberg, where he devoted himself entirely to literature. His first work, entitled Théorie du Pouvoir Politique et Religieux, was published at ConBonaven-

Bonaparte stance in 1796, but was interdicted by the French Directory. It was republished at Paris in 1843. Though a staunch supporter of the Bourbons, Bonald returned in 1804 to Paris, where he supported himself for many years by his pen, refusing various advantageous offers from the family of In 1815 he was chosen deputy for Aveyron, and distinguished himself by his efforts to check the abuses of the press. In 1823 he was nominated a peer of France, and accepted office under the government; but he lost both his title and his place by refusing to take oath to the new government of 1830. In that year he retired to his birthplace, where he died on the 23d November 1840, at the age of eighty-six. His philosophical, social, and political theories are based on this proposition, "L'homme pense sa parole, avant de parler sa pensée. Loin que la parole soit le produit de la pensée c'est elle-même qui en est le principe. Or, si la parole est antérieure à la pensée d'ou peut elle venir, si non de Dieu même?" The principal works of M. Bonald, besides that already mentioned, are La Législation Primitive, Paris, 1821, 3 vols. 8vo; Recherches Philosophiques sur les premiers Objets des connaissances morales, 2 vols. 8vo, 1818 and 1826; Démonstration Philosophique du principe constitutif de la Société, Paris, 1830, 8vo.

BONAPARTE, or BUONAPARTE. See NAPOLEON. BONARELLI, DELLA ROVERE, COUNT GUID' UBALDO, an Italian poet, born at Urbino, A.D. 1563, was the son of Count Pietro Bonarelli, minister of the Duke of Urbino. He was intrusted with several important negotiations, and was esteemed an able politician and learned philosopher. He was the author of a pastoral entitled Filli di Sciro, printed for the first time at Ferrara in 1607, with cuts, 4to; and of an amatory production entitled Discorsi in difesa del doppio Amor della sua Celia, first printed at Ancons in 1612, 4to. He died at Fano in 1608. His brother Prospero and his

nephew Pietro were also writers of poems, &c.

BONASONE, Giulio, an admirable engraver, born at Bologna about 1498. He studied painting under Lor. Sabbatini, but attained small proficiency in that branch. The freedom and expression, however, of his etching needle and burin are most excellent, and we owe to him engravings from the works of Michael Angelo, Raffaello, Titian, and many other illustrious painters, that will always hand down his name as among the most eminent in that department of the arts.

BONASSUS. See Mammalia, Index.

BONAVENTURE (Bonaventura) St, one of the brightest luminaries of the scholastic age, was born of a good family, at Bagnarea in Tuscany, in 1221. His original name was Giovanni di Fidenza, but from a particular incident in his childhood he received the name by which alone he is now generally known. In 1243 he entered the order of St Francis, and after several years' study at Paris under the celebrated Alexander of Hales, he was in 1253 appointed to lecture publicly on the Sentences of Lombard. In 1255 he took his doctor's degree on the same day with Aquinas. The year following he was chosen general of his order, which he governed till his death with vigour and prudence. He is said to have declined the offer of the see of York from Clement IV. in 1265; and might on the death of that pope have been elected in his stead, the cardinals having solemnly engaged themselves to abide by the choice of Bonaventure, even if he should nominate himself. The person whom he recommended was Theobald, archdeacon of Liège, at that time in the Holy Land. The new pope, who assumed the name of Gregory X., appointed Bonaventure in 1273 to the bishopric of Albano, and soon after raised him to the dignity of a cardinal. Bonaventure died July 15. 1274, while attending the second council of Lyons as legate of the pope. His remains were attended to the tomb by the pope and the whole council: they were exhumed in the sixteenth century by the Huguenots, burnt, and cast into the Saône.

Bonaventure was canonized in 1482 by Sixtus IV., and

ranked in 1587 by Sixtus V. as the sixth great doctor of Bonavista the church. The city of Lyons chose him as her patron saint. The purity and gentleness of his character, and the Bondman. heavenly thoughts with which his writings abound, procured him among scholastic divines the title of the seraphic doctor. By the Franciscans he is regarded as the greatest doctor of their order, and held up as a rival to St Thomas, the glory of the Dominicans. His works, printed at Rome 1588-96, in eight vols. folio, comprise commentaries on the Scriptures and on the Book of Sentences, numerous tracts chiefly on ascetic and practical subjects, sermons, letters, &c. This collection includes several apocryphal works, among which is the famous Psalter of the Virgin. His efforts to make philosophy (which with him is a combination of Peripateticism and Neoplatonism) subservient to faith, resulted in a pious mysticism which makes his meaning often obscure. Union with God he regards as the sovereign good, and this principle he has developed in his Itinerarium Mentis in Deumand his Reductio artium in Theologiam. The latter treatise is devoted to a proof of the thesis that theology is the final consummation of all science and art. Bonaventure is distinguished above all the schoolmen by his freedom from trivial subtleties, his religious fervour, and the practical tendency of his spirit. His commentary on Lombard contains a most acute refutation of the doctrine of the eternity of the world, and some new arguments for the immortality of the soul. He is eulogized by Luther as an excellent man (Bonaventura, præstantissimus vir); and characterized by Bellarmin as a doctor alike beloved by God and man.

BONAVISTA, or BOAVISTA, an island near the western coast of Africa, forming part of the group called Cape de Verd, from their vicinity to that remarkable promontory. It was the first of the number discovered by the Portuguese in 1450. Captain Porter describes the island as consisting of a level plain, rising in the centre into rugged and rocky A great part is capable of cultivation, and eminences. might yield in abundance cotton and indigo, were these properly attended to by the indolent natives. Pop. 4395, chiefly engaged in the manufacture of salt. There are three good roads for shipping. The north-west point is in Long.

22. 56. 24. E. and Lat. 16. 13. 18. N.

BOND, John, a commentator on Horace and Persius, was born in Somersetshire in 1550, educated at Winchester school, and at New College, Oxford, by which society he was appointed master of the free school at Taunton. In this situation he acquired some reputation; but growing weary of teaching he applied to physic, and practised, it is said, with considerable success. He died in 1612. short marginal annotations upon Horace and Persius (1606 and 1614, 8vo) are generally feeble, and without erudition; yet his edition of the former has often been reprinted. Saxius describes him as minorum gentium philologus.

BONDAGE properly signifies slavery, but in old law Tenants in bondage paid books it is used for villenage. kenots, did fealty, and were prohibited from felling trees in their own garden, without license of the lord. The widow of a tenant in bondage held her husband's estate quamdiu

vixerit sine marito, as long as she lived single.

Bondage by the Forelock, or Bondagium per anteriores crines capitis, was when a freeman renounced his liberty, and became a slave to some great man, which was done by the ceremony of cutting off a lock of hair from the forehead, and delivering it to his lord. If he reclaimed his liberty, or became fugitive from his master, he might be drawn again to his servitude by the nose, whence the origin of the popular menace to pull the nose.

BONDMAN, in Old English Law, a villain, or tenant in villenage. The Romans had two kinds of bondmen; one, called servi, who were those either bought for money, taken in war, left by succession, or acquired by some other lawful title; the other, born of their bondwomen, and called

Bondou

vernæ. We may add a third kind of bondmen mentioned by Justinian, called adscriptitii glebæ, or agricensiti, who were a species of serfs or boors, not bound to the person, but to the ground or place, and who followed him who had the land. These in our old law are called vilains regard-

ants, as belonging to the manor or place.

BONDOU, a kingdom of Western Africa, between 14. and 15. N. Lat., and 11. and 13. W. Long. The country is elevated, and the mountains are generally unproductive, and covered with stunted wood. The intervening valleys, however, are fertile, and finely clothed with the baobab, the tamarind, and various valuable fruit trees. They are traversed by beds of torrents, which flow rapidly during the rains, but are empty in the dry season. Cultivation, though it extends over only a comparatively small proportion of the whole surface, is carried on with considerable activity. The products consist of four species of grain, rice, cotton, indigo, and fruits. The workmen in the different parts display considerable dexterity, though they employ very rude and defective tools. The people consist chiefly of Foulahs, though the country is much frequented by Mandingoes and Serawoollies for purposes of trade. The exports consist of provisions and cotton cloth manufactured in the country, in exchange for slaves and salt. The caravans, bringing the former from the interior to the coast, pass usually through Bondou.

The religion and laws of this country are Mahommedan, though the precepts of that faith are not observed with the same rigour as in more northern countries. There are schools, however, in every town, where the Koran and the reading and writing of Arabic are taught; but the scholar is treated as the servant of the teacher, for whom he is obliged to perform the most menial offices. The king is nearly absolute, and commands a considerable body of troops, who are much employed in predatory expeditions, chiefly for the purpose of collecting slaves. His revenues are derived from a tenth part of the produce of the land, and of the salt imported, as also from duties on goods passing through his territories, with numerous presents expected or extorted. Mr Park experienced to his cost the rapacity of the reigning prince, being obliged to give up even the coat which he wore. He was introduced to the king's twelve wives, who had never before seen a European, and thought that the white skin had been produced by his having been bathed in milk by his mother, who had also artificially pinched up his nose into its unnatural elevation. The royal residence was then at Fatteconda; but when Major Gray visited Bondou it had been removed to Boolibani, a small town surrounded by a strong clay wall. The palaces of the king and his sons consist merely of inclosures about an acre in extent, containing a number of cottages, somewhat larger, but not more commodious, than those of his subjects.

BONE DUST. See AGRICULTURAL CHEMISTRY.

Bone, Henry, R.A., the most eminent enamel painter of Great Britain, was born at Truro in 1755. He was much employed by London jewellers for small designs in enamel, before his merits as an artist were well known to the public. In 1800 the beauty of his pieces attracted the notice of the Royal Academy, of which he was then admitted as an associate, and in 1811 as an academician. From the beginning of this century until 1831, he executed many beautiful pieces of much larger size than had been attempted before in this country: among these his 85 portraits of the time of Queen Elizabeth, of different sizes, from 5 by 4, to 13 by 8 inches, are most admired. They were disposed of by public sale after his death, which took place in 1834. His "Bacchus and Ariadne," after Titian, painted on a plate, brought the great price of 2200 guineas.

BONES. See ANATOMY and Index.

Bones of the Dead. Different usages and ceremonies relating to the bones of the dead have obtained in different ages; as gathering them from the funeral pile, washing,

anointing, and depositing them in urns, &c. Among the ancients, the bones of travellers and soldiers dying in foreign countries were brought home to be buried; but during the Italic war this was prohibited by the senate.

The Romans acknowledged a deity, called Ossipaga, or Ossipanga, to whom the care of the induration and knitting of the human bones was committed, and who on that account

was invoked by pregnant women.

BONET, or BONNET, THEOPHILUS, an eminent physician, born at Geneva, March 5. 1620. He took his degree in 1643, and then applied himself to the practice of his profession, in which he acquired great reputation. On retiring from practice, he found leisure to collect all the observations he had made during an experience of forty years. But his principal title to distinction is rather as a medical writer than a practitioner, and as having in some measure created pathological anatomy, which Morgagni afterwards illustrated. He died March 29. 1689. His most valuable work is Sepulchretum, sive Anatomia Practica ex cadaveribus morbo denatis, a valuable mine of morbid anatomy. The best edition is that of Magnetus, Geneva, 3 tom. folio, 1700. His other works are, Mercurius Compitalitius, Geneva, 1682, fol.; Zodiacus Medico-Gallicus; Medicina Septentrionalis Collatitia, Geneva, 1684-86, 2 vols. fol.; Polyanthes, sive Thesaurus Medico-Practicus, Geneva, 1690-93, 3 vols. fol.; Theodori Turqueti de Mayerne Tractatus de Arthritide, Geneva, 1671, 1674, 12mo, Jacobi Rohaultii Tractatus Physicus, Geneva, 1674, 8vo, both translations; Bibliothèque de Médecine et de Chirurgie, Geneva, 1670, 4 vols.

BONFADIO, Jacopo, a celebrated Italian writer, born at Gazano, in the diocese of Brescia, about the commencement of the 16th century. He was secretary to Cardinal Merinos, archaishop of Bari, and afterwards to Cardinal Ghinucci at Genoa. He read public lectures on Aristotle's politics, and on rhetoric, and was appointed professor of philosophy and historiographer to that republic. He had completed five books of the annals of that state, which were to have been followed by others; but having spoken too freely of some noble families, they resolved upon his ruin, and accused him of an unnatural crime. As witnesses were found to convict him, he was condemned to the flames; but the sentence was commuted, as an act of special grace, into beheading. This took place in 1550. Authors have varied in their opinions as to Bonfadio's alleged guilt; Tiraboschi among others, maintains the affirmative of the question. His works are, 1. Annalium Genuensium ab anno 1528 Recuperatæ Libertatis usque ad annum 1550, libri quinque, Pavia, 1586, 4to; 2. Lettere Famigliari di Jacopo Bonfadio, con altri suoi Componimenti in prosa ed in verso, with a life of the author by Mazzuchelli, Brescia, 1746, 8vo.

BONFINI, ANTHONY, a Latin historian, born at Ascoli, in the marquisate of Ancona, in December 1472. His literary fame induced Matthias Hunyadi, king of Hungary, to invite him to his court, where he was retained and pensioned by that sovereign, as well as by his successor Wladislaus. He wrote by royal command the early history of Hungary, which he brought down to the year 1495. It is a well-executed work, and has gone through several editions. Bonfini died in 1502. He has left, 1. Rerum Ungaricarum decades tres, Basle, 1545, fol.; 2. Flavii Philostrati Lemnii Libri ii. de Vitis Sophistarum, 1516, 4to; 3. Hermogenis Libri de Arte Rhetorica et Aphthonii Sophistæ Progymnastica, Lyons, 1538; 4. In Horatium Flaccum Commentarii, Rome, without date, 4to; and, 5. Symposion Beatricis, Basle, 1572 and 1621, 8vo.

BONFRERE, JACQUES, in Latin Bonfrerius, a learned Jesuit, born at Dinant-sur-Meuse in 1573. He wrote a commentary on the Pentateuch, and notes on the Onomas-

ticon, or description of the places and towns mentioned in Scripture. He died at Tournay in 1643.

BONGARS, or Bongarsius, Jacques, counsellor and

Bonet Bongars.

Boni Boniface. maitre d'hotel to Henri IV., and one of the ablest critics of his time, was born at Orleans in 1546. He studied the belles-lettres at Strasburg under an anabaptist professor, and law at Bourges under Cujas. He was for about thirty years employed in the most important negotiations of Henri IV. at the courts of the princes of Germany, first as resident, and afterwards as ambassador. Bongars was a Protestant, and happening to be at Rome when Sixtus V. fulminated his famous bull of excommunication against Henri IV., he wrote a spirited answer, which he had the boldness to post up in a conspicuous place, and which was afterwards published with his name in the Mémoires de la Ligue. He died at Paris July 29, 1612. His printed works are, 1. A Collection of the Historians of the Crusades, under the title of Gesta Dei per Francos, Hanau, 1611, fol.; 2. Jacobi Bongarsii Epistolæ, Lugd. Bat. 1641; 3. Collectio Hungaricarum Rerum Scriptorum, Francf. 1600, fol.; 4. An edition of Justin, with learned notes; besides notes on Petronius, and various readings of Paulus Diaconus.

BONI, or Bony, a state in the island of Celebes, stretching for part of its extent along the western shores of a great cognominal bay which indents the southern side of the island to the depth of nearly 180 miles. The inhabitants of this once powerful and independent country are the Bugis,-a people in many respects the most remarkable of the Eastern Archipelago. Their numbers, by the Dutch census in 1824, amounted to about 200,000. Living, as they do, surrounded by nations notorious for treachery, piracy, and indifference to the arts and objects of civilized life, they have always shown themselves honest, industrious, and ingenious. Agriculture is by them more extensively practised than by any of the adjoining tribes; and of the cotton cloth called cambays worn in these regions, they not only manufacture enough for their own use, but also export considerable quantities to the Malay islands. They likewise carry on a considerable traffic in the mineral and vegetable productions of their country, such as gold dust, tortoise-shell, pearls, nutinegs, camphor, and various medicinal preparations; and for these they find a ready market at Singapore, the chief commercial entrepôt of these Eastern seas. In the form and constitution of their government, likewise, they approach more nearly the spirit of true civilization than any other Asiatic people. The highest officer of state is the king or president, who is elected generally for life, and always from their own number, by the chiefs of the eight petty states that compose the nation. His power, however, is so limited that he cannot decide upon any measure of public polity, without the consent of the minor chiefs by whom he was originally appointed. In some of the petty states the office of chief is the hereditary prerogative of a family; in others any member of the privileged classes may aspire to that dignity. Hence it happens not unfrequently that the state comes to be governed by a woman, as the principle of the Salic law is here unknown. Of the history of Boni not much is known. According to Temminck, it first acquired importance in the year 1666, when the rajah Palakkah, whose father and grandfather had been murdered by the family of Hassan the tyrant of Sumatra, made common cause with the Dutch against that despot. From that date till the beginning of the present century the Dutch influence in the polity of the kingdom remained undisputed. In 1814, however, Boni fell into the hands of the British, who retained it for two years; but by the European treaties concluded on the downfall of Napoleon it reverted to its original colonizers.

BONIFACE, the name of several eminent men, particularly of nine popes. To the first of these, who was chosen pope in December 418, St Augustin dedicated his four books in answer to the two epistles of the Pelagians.—Boniface II. was elected pope in October 530, and succeeded Felix IV., who had been nominated by a part of the clergy, the senate, and the people assembled in the basilica of Con-

stantine, and whose memory he caused to be condemned. Boniface His pontificate was distinguished only for its turbulence.-Boniface III. was elected in February 606. He prevailed upon the emperor Phocas to consent that the title of Universal Bishop should be conferred on no other but the bishop of Rome, and that the Holy See should have the supremacy over that of Constantinople.-Boniface IV., raised to the papal chair in August 608, obtained from the same emperor the Pantheon, or temple of all the gods, built by Agrippa, and converted it into a church, which he consecrated to all the martyrs and the Virgin, under the name of Santa Maria della Rotonda.—Boniface V. was elected in December 618, and died in October 624.—Boniface VI was elected in April 896, but died of the gout fifteen days thereafter.-Boniface VII., called Franco, is styled an antipope. He was suspected of having caused Benedict VI. to be strangled in prison in 974; and after the election of Benedict VII. he removed the treasures of the church to Constantinople. He returned on the death of Benedict, whose successor John XIV. was disposed of in the same way as Benedict VI. This intruder died in December 985. -Boniface VIII., a pontiff conspicuous for his pretensions to temporal authority, was elected in December 1294. He canonized St Louis in 1297, and in 1300 appointed the jubilee to be solemnized every hundred years thereafter.— Boniface IX. was elected pope on the 2d November 1389, after the death of Urban VI., and during the schism of the west. He supported Ladislaus of Hungary in his pretensions to the kingdom of Hungary, against Louis of Anjou, protected by the Avignon pope, Clement VII. Some writers have praised his moral character; but the greater number have accused him of simony, of cupidity in order to enrich his family, and of exactions for the support of his government. He died on the 1st October 1404.

Boniface, a saint designated as the Apostle of Germany, was an Englishman, by name Winifrid, and was born in Devonshire, A.D. 670. He went to preach the gospel among the barbarous nations of Germany; and although created archbishop of Mayence, he soon after resigned his office, in order to preach in East Friesland, where during a tumult he was murdered by the pagans, June 5. 755. With him also perished Eoban a bishop, three priests, three deacons, four monks, and forty-eight laics. The Bollandists collected the Acta Bonifaciana, containing an account of the miracles of the saint; and a collection of his Letters, amounting to 152, was published by Serrarius in 1605, 4to. In the Spicilegium of D'Achery may be found the canons which he promulgated for regulating the conduct of his clergy; and one of his sermons is preserved in the Thesaurus Anecdotorum Novissimus, tom. iii. part 2, published by D. Bernard Pez, at Augsburg, 1729.

BONIFACIO, a town in the island of Corsica, beyond the mountains, near the strait called Bocca di Bonifacio. It is well fortified, and has a secure harbour, with some trade. Pop. 3120. Long 9. 9. 16. E. Lat. 41. 23. 10. N.

BONN, the chief town of the circle of the same name in Rhenish Prussia, is pleasantly situated on the left bank of the Rhine, 15 miles S.S.E. of Cologne, with which it is connected by railway. The town has several good streets and a fine market-place. A statue of Beethoven, who was born here on the 17th December 1770, was erected, in 1844, in one of the squares. The cathedral is a fine old edifice in the Byzantine style, surmounted by five towers. Bonn is chiefly celebrated for its university, established by the king of Prussia in 1818, and occupying the extensive palace of the electors of Cologne. It has faculties of philosophy, law, medicine, and theology, both Protestant and Roman Catholic. The number of students in 1849 was 833, of whom 116 were foreigners. It has numbered among its professors Niebuhr and A. W. Schlegel, and among its students, H.R.H. Prince Albert. The library contains about 150,000 volumes. A beautiful avenue of chestnut trees, about a mile in length, extends

Bonnefons from the university to the chateau of Poppelsdorf, which contains a valuable museum of natural history, and has attached to it a spacious botanic garden. Bonn has one Protestant and three Roman Catholic churches, a synagogue, a gymnasium, and riding-school. Pop. (1849), including the military, 17,688, of whom 14,725 are Catholics. Its principal manufactures are cotton, silk, tobacco, and soap; and it has a considerable trade in wine, grain, &c. The circle has a population of 55,872.

BONNEFONS, or Bonefonius, Jean, a Latin poet, born at Clermont in Auvergne, A.D. 1554. He studied law under Cujas at Bourges; became an advocate in the parliament of Paris; was appointed lieutenant-general of Bar-sur-Seine; and by his poems acquired great but unmerited reputation, especially by his Pancharis, written in the style of Catullus. He died in 1614. He must not be confounded with John Bonnefons, his son, another Latin poet, nor with Dom Elia Benedict Bonnefons, a learned Benedictine of the congregation of St Maur, who died in 1702. The most complete edition of Bonnefons' works is that of Amsterdam, 1767, 12mo, entitled, Joannis Bonnefonii patris, Arverni, Opera Omnia.

BONNER, or Boner, EDMUND, an English prelate, notorious for his persecutions of the Protestants during the reign of Queen Mary, was born at Hanley in Worcestershire about the end of the fifteenth century, and generally passed for the natural son of George Savage, a priest, who was the natural son of Sir John Savage of Clifton in the same county. Strype, however, says he was positively assured that Bonner was the legitimate offspring of a poor man, who lived in a cottage long afterwards known by the name of Boner's Place. About the year 1512 he entered as a student of Broadgate Hall (now Pembroke College), Oxford; and in 1519 was admitted as bachelor of the canon and of the civil law. Having been admitted into orders, he obtained some preferment in the diocese of Worcester. In 1525 he took his degree as doctor; and having attracted the notice of Wolsey, that prelate took him under his patronage. Bonner was with the cardinal at Ca-wood when he was arrested on a charge of high treason. After the death of Wolsey he saw his way towards adopting Lutheran sentiments, and found means to insinuate himself into the favour of Henry VIII., who made him one of his chaplains, and employed him in several embassies abroad. In 1532 he was sent to Rome with Sir Edward Carne, to answer for the king, who had been cited to appear in person or by proxy. In 1533 he was again despatched to Pope Clement VII., then at Marseilles, to intimate Henry's appeal to a future general council from the sentence which had been pronounced against his divorce. On this occasion he threatened the pope with so much resolution, that His Holiness talked of having him burned alive or thrown into a cauldron of melted lead. Bonner accordingly judged it prudent to decamp without the ceremony of taking leave. His Holiness did not foresee that the man whom he had thus menaced with the flames was destined to burn heretics in England in support of the very faith which, under Henry, he had lent his aid to overthrow. In 1538, being then ambassador at the court of France, he was nominated bishop of Hereford; but, before consecration, he was translated to the see of London, and enthroned in April 1540. Henry VIII. died in 1517, at which time Bonner was ambassador at the court of the emperor Charles V. During this reign he was constantly zealous in his opposition to the pope; and, in compliance with the king, favoured the Reformation. Henry VIII. was a man to exact a rigid compliance with all his whims and caprices; but on the accession of young Edward, Bonner refused to take the oath of supremacy, and was committed to the Fleet, where he remained until he thought fit to promise obedience to the laws. After his release he continued to comply with the Reformation, but with such manifest neglect and reluctance, that he was twice reprimanded

by the privy council, and in 1549 was, after a long trial, Ronnet. committed to the Marshalsea, and deprived of his bishopric. The succeeding reign, however, gave him ample opportunity of revenge. Mary was scarcely seated on the throne when Bonner was restored to his bishopric, and soon afterwards appointed vicegerent and president of the convocation. From this time he became the chief instrument of persecuting cruelty, and is said to have condemned no less than 200 Protestants to the flames in the space of three years. Nor was this vindictive and persecuting priest less remarkable for his impudence than his cruelty. On the accession of Elizabeth lie appeared with the rest of the bishops at Highgate, to congratulate her on the occasion; but the queen refused to permit him to kiss her hand. Having, in the second year of her reign, refused to take the oath of allegiance and supremacy, he was again deprived and committed to the Marshalsea, where he died, Sept. 5. 1569, after a confinement of ten years' duration. The character of Bonner was remarkable for obstinacy and inflexibility in everything save principle; yet even in this respect it exhibits some striking contrasts. In the early part of his career he accommodated his principles to his convenience and ambition; in the latter, after his return to Catholicism, he remained stedfast in his adherence to the church, and, when disgraced, bore his deprivation and imprisonment with apparent calmness and resignation. The charge of atheism brought against one so defiled with blood was superfluous. He was constitutionally merciless and austere; fitted by nature for a persecutor of all opinions adverse to his own; and equally capable of employing the same burning zeal either against or in favour of any cause that he esponsed.

BONNET, CHARLES, an eminent naturalist and philosophical writer, born at Geneva on the 13th March 1720, of a French family whose religious principles had obliged them to leave their native country. At the early age of sixteen his attention was so deeply engaged by the study of Pluche's Spectacle de la Nature, that it seems to have given a bias to his future studies. The history and habits of the antlion, formica leo, particularly attracted his attention. He discovered the haunts of this curious insect, studied its habits, and added many observations to those of Pluche and Reaumur. Reaumur's memoir on Insects he also perused with great avidity; and to the observations and experiments of that naturalist Bonnet added many new facts, the detail of which he communicated to Reaumur; who was not less surprised than pleased to find so much sagacity and acuteness of research exhibited by a youth of eighteen.

Bonnet had been destined by his father for the profession of the law; but the bias of his mind leaned too strongly to natural history to permit him to occupy his attention with other pursuits, and the study of law was submitted to merely as a task. In 1738 and 1739 he sent to Reaumur many interesting observations on different species of caterpillars; and in 1740 he communicated a paper to the Academy of Sciences respecting the propagation or multiplication of aphides, or tree-lice, without actual conjunction. This question, which had been left unsettled by Reaumur, was now determined by decisive experiments; and his paper on the subject obtained for Bonnet the honour of being admitted a corresponding member of the Academy. His experiments on the generation of these insects were conducted with such close attention and minuteness of research as permanently to affect his eyesight. In the year 1741 he instituted a set of experiments on the division of worms; and he found that many species possessed in some degree the same reproductive power as the polypus. In the following year his investigations and experiments were directed to the respiration of caterpillars and butterflies; and he proved that this function was performed by means of pores to which the name of stigmata has been given. It was about the same time that he made some curious discoveries respecting the tænia, Bonnet.

or tape-worm. In 1743, when he became a doctor of laws, he procured a ready dispensation from the further prosecution of his legal studies, which he now relinquished for ever. A memoir on insects which he communicated to the Royal Society of London in the same year procured his admission into that body. Next year he published his *Insectology*, and prefixed to it a preface, in which he exhibits a philosophical sketch of his ideas concerning the system of the development of germs, and the scale of organized beings. This work was in general well received, though by some of the journals it was taxed with a want of delicacy in the descriptions of the mode of propagation of tree-lice.

Bonnet's health now began visibly to decline. His eyes particularly were affected with severe pains, which obliged him to lay aside the use of the microscope, and to forego for a time all reading and writing. Like a true philosopher, he bore his afflictions with patience; yet, although he was interdicted from all observation, his mind was fully occupied in reflection. He was at last restored to tolerable health; but he never could employ his eyes with the same freedom as formerly. About the year 1746 he undertook a course of experiments on the vegetation of plants in moss and other substances; and in the following year his researches were directed to the functions of the leaves of plants, with the view of ascertaining the different action of the two sides of the leaf. He also made experiments on the ascent of the sap; and to determine whether it rose by the bark or wood, he employed coloured injections. This investigation, with some observations which he made on vegetable monsters, was the foundation of one of his most interesting and original works, entitled Inquiries into the use of the Leaves of Plants, Leyden, 1754, 4to. A supplement was added to it in 1779.

Bonnet's inquiries in natural history now led him on to physiology and metaphysics, where he followed in the footsteps of Malebranche and Leibnitz. The first fruit of his meditations was a kind of abridgment of the materials he had collected, under the title of an Essay on Psychology, published in London in 1754, but without his name, nor did he acknowledge it till nearly thirty years afterwards. This work contains, in a concise form, the fundamental principles of his philosophy; some account of which will be found in Mr Stewart's Dissertat., part ii., §§ 2, 3, 5. It met with some censure, yet its success was brilliant. His next work was a development of the same subject. In 1760 he published, at Copenhagen, in 4to, his Analytical Essay on the Faculties of the Soul, in which, like Condillac, he supposes a statue organized like the human body, which by degrees he animates, and shows how its ideas would arise from impressions on the organs of sense. This essay was well received, though it subjected the author to a charge of materialism, which it cannot be denied was the logical result of its principles. In the case of Bonnet, however, the charge was of easy refutation. His retired and studious habits, together with his deafness and other bodily infirmities, rendering domestic comforts more essential to him, he married, in 1756, a lady of the family of De la Rive, and with her he passed thirty-seven years of domestic happiness. The celebrated Saussure was nephew to his wife, and was brought up as a son by Bonnet, who had no children of his own.

His next work, Considerations on Organized Bodies, 2 vols. 8vo, Amst. 1762, was properly the physical part of his great system. Its principal objects were, to give in an abridged form all the most interesting and well-ascertained facts respecting the origin, development, and reproduction of organized bodies; to refute the different systems founded upon epigenesis; and to explain and defend the system of germs. His Contemplation of Nature, Amst. 1764-65, 2 vols. 8vo, was a popular work, in which the principal facts relative to the different orders of created beings are displayed in a manner both instructive and entertaining, and set off

by the charms of an eloquent style; with a continual refermence to final causes, and proofs of creative wisdom and benevolence. It has been translated into most of the European languages. The concluding work of Bonnet was his Palingénésie Philosophique, Geneva, 1769, 2 vols. 8vo. In this he treats of the past and future state of living beings, and supports the idea of the survival of all animals, and the perfecting of their faculties in a future state. Attached to this work is An Inquiry into the Evidences of the Christian Revelation, and the Doctrines of Christianity, which, with a treatise On the Existence of God, was published separately at Geneva in 1770 and 1771.

Again directing his attention to natural history, he published in 1773, in Rozier's Journal, a memoir on the method of preserving insects and fishes in cabinets; and, in the following year, another on the loves of plants, originating in the discovery of a kind of cleft or mouth in the pistil of a lily. This was followed by various memoirs and observations on subjects in natural history. His reputation was now fully established. Most of the learned societies of Europe enrolled him among their members; and in 1783 he was elected into the small and very select number of foreign associates of the Academy of Sciences at Paris. Although attached by inclination to scientific pursuits, he did not entirely withdraw from public duties. He entered into the great council of the republic in 1752, and kept his seat in it till 1768; having frequently distinguished himself by his manly eloquence in support of moderate measures, and his zeal in the cause of morals and religion. The last twenty-five years of his life he passed entirely in the country, in a simple and uniform mode of life, happy in an easy competence, and in a small circle of friends. It appears that he was for some time engaged in the education of youth, in which employment he secured the warmest attachment of his pupils. His health was greatly impaired by the excessive labour he bestowed for nearly eight years on a collective edition of his works. This appeared at Neufchâtel in 1797, in 8 vols. 4to, and 18 vols. 8vo. Besides the works already mentioned, it contains a number of smaller pieces, both in natural history and metaphysics. They are all written in French. After a long and painful illness, which he bore with exemplary patience and serenity, this excellent man died on the 20th May 1793, at the age of seventythree. Public honours were rendered to his remains by his fellow-citizens, and his funeral oration was pronounced by his illustrious friend and kinsman M. de Saussure.

BONNEVAL, CLAUDE ALEXANDRE, COMTE DE, known afterwards as Achmet Pasha, was descended from an illustrious family of Limousin, and was born July 14. 1675. He entered at the age of sixteen into the service of the crown, and married the daughter of Marshal de Biron. He distinguished himself at the combats of Dieppe, La Hogue, and Cadiz; and he made the campaign of Flanders in 1690. He soon after left the French army, and, entering into the imperial service under Prince Eugene, signalized himself greatly on several occasions, particularly at the battle of Peterwardin, where the victory was due in a great measure to his intrepidity. The intrigues of the Marquis de Prie, however, ruined his credit at the court of Vienna, and caused him to be banished the empire. He then offered his services to the republic of Venice and to Russia; and these being declined in both instances, his next tender was to the Sultan, who gladly received him. It was stipulated that he should have a body of 30,000 men at his disposal; that a government should be conferred on him, with the rank of pasha of three tails, and a salary of 10,000 aspers a-day; and that, in the event of war, he should be commander-inchief. The first expedition he engaged in after his arrival at Constantinople, was to quell an insurrection in Arabia Petræa, which he happily effected. On his return he had large offers made him by Kouli Khan, which, however, he

Boodroom.

did not choose to accept. Some time after, he commanded the Turkish army against the emperor, over whose forces he gained a victory on the banks of the Danube. Bonneval afterwards fell into disgrace, and notwithstanding his services, was first imprisoned, and then banished to the island of Chio. The sultan, however, continued his friend; and, the evening before his departure, made him pasha of the Archipelago, which, with his former appointment of beglierbey of Arabia, rendered him one of the most powerful persons in the Ottoman empire. In this island he found a retirement quite agreeable to his wishes, but was soon recalled, and made topidgee or master of the ordnance, a post of great honour and profit. He died in 1747. Doubts have been thrown on the genuineness of the Mémoires du Comte de Bonneval, purporting to be his autobiography.

BONNYCASTLE, Joun, an eminent English mathematician, long professor of mathematics at Woolwich, and well known by his valuable Elements of Algebra, in 2 vols. 1813, his Guide to Arithmetic, and other works. He died

in 1821.

BONONCINI, or Buononcini, Giovanni Maria, of Modena, a composer of music in the seventeenth century, whose merit as compared with that of Handel for some time caused a division of public opinion. Bononcini was also the author of a work entitled Il Musico Pratico, published in 1673, and translated into German in 1701.

BONONIA. See Boulogne.

Bononia, a town in Pannonia Inferior, between Meursa to the N.W. and Taurinum to the east; also a town in Mœsia Superior, on the Danube, now Bonus in Bulgaria.

BONVINCINO, or Bonvicino, Alessandro, called IL Moretto, an eminent Italian painter, born at Brescia, A.D. 1514. He was originally a pupil of Titian, whose style he imitated admirably; and afterwards, by the diligent study of Raphael's works, he united in some degree the peculiar excellencies of both those masters. His works were eagerly bought up, being admired for the tenderness of the penciling, the correctness and expression of the figures, and the rich variety of the draperies. He was also excellent in portrait, and by many was placed in competition even with Titian himself. He died in 1564.

BONZES, a general term employed by Europeans to denote the sacerdotal orders of China, Japan, Cochin-China, Burmah, &c., but more particularly applied to the priests of the two first-named kingdoms. The bonzes, like the Catholic priests, practise celibacy, and some of them, like the ancient monks, live in monasteries. Some of their orders are remarkably superstitious, and pay homage to symbolic figures, and not unfrequently to hideous idols. Far from enlightening their countrymen, they mystify them by the practice and inculcation of their ridiculous devotions; and being grossly ignorant themselves, they cannot be expected to dispel the thick darkness in the midst of which they live. Some of them lead lives of contemplation and reflection, and if they do no positive good, set a praiseworthy example by the purity of their lives. In the eighteenth century, the philosophes often allegorically designated the clergy of the Latin church under the name of bonzes, whom they represented as intolerant bigots. The allegory, however, was unjust, for the bonzes, though they disdain other forms of worship than their own, bear no personal ill-will to those that practise them. They differ still more from the clergy of most Christian countries in this, that in civil affairs they have neither influence nor authority of any kind.

BOODROOM, or BAUDRUN, a small town of Anatolia, in Asia Minor, situated at the bottom of a deep bay. It is supposed to occupy the site of the ancient Halicarnassus, and the vicinity abounds with many relics of antiquity. houses are irregularly built along the shore, and are inter-

and in different parts of the bazaar, are scattered fragments of columns and mutilated sculptures. The castle stands on a broad square rock, which projects into the bay, and has a small harbour on the western side, which, though it has fallen into decay, is still convenient and safe, and is frequented by Turkish cruisers. This castle is adorned with the most exquisite sculptures in different parts of the walls, and is said to have been built by the knights of Rhodes in 1402. There are still some traces of the ancient walls, and above the town are the remains of a theatre, about 280 feet in diameter, which appears to have had thirty-six rows of marble seats. Near the harbour is the palace, with some small mosques. Pop. about 11,000, consisting chiefly of Greeks and Turks. Long. 27. 33. E. Lat. 37. 7. N.

BOOK, the common name for any literary production of bulk; but more particularly applied to a printed composi-

tion forming a volume.

Various substances have been used for writing upon; such as plates of lead and copper, the bark of trees, bricks, stone, wood, &c. Josephus speaks of two columns, the one of stone and the other of brick, on which the children of Seth wrote their inventions and astronomical discoveries; and Porphyry mentions some pillars preserved in Crete, on which the ceremonies observed by the Corybantes in their sacrifices were recorded. Hesiod's works were originally written upon tablets of lead, and deposited in the temple of the Muses, in Bœotia; the ten commandments delivered to Moses were written upon stone; and the laws of Solon were inscribed upon wooden planks. Tablets of wood and of ivory were common among the ancients; but when of wood, they generally received a coating of wax, on which the let-The leaves of the ters were traced with a pointed style. palm-tree were afterwards used instead of wooden tablets; and also the inner bark of such trees as the lime, the ash, the maple, and the elm; whence the word liber, literally the inner bark of a tree. As these barks were rolled up, the rolls were called volumen, a volume; a name afterwards given to similar rolls of paper or parchment.

The first writing was upon blocks and tablets; but when flexible matter came into use it was found more convenient to make books in the form of rolls, which were composed of several sheets fastened to each other, and rolled upon a staff, the whole forming a kind of cylinder. The ends of the staff-were usually ornamented with bosses of wood or ivory, and sometimes of silver, and even gold and precious stones. The title (titulus index) was either suspended to the roll or pasted on the outside; and the whole volume, when extended, might be about a yard or more in breadth, and sometimes fifty in length. The square form composed of separate leaves was also known, though little used by the ancients.

The internal arrangement of books has undergone many modifications. At first the letters were divided only into lines; then into separate words; and these, by degrees, were noted with accents, and distributed by points and stops, into periods, paragraphs, chapters, and other divisions. some countries, as among the orientals, the direction of the lines was from right to left; in others, as among the northern and western nations, from left to right; while the early Greeks followed both directions, writing alternately from right to left and from left to right, which was called boustrophedon, from its analogy to the path of oxen in ploughing. In this manner Solon's laws were written. In most countries the lines run from one side to the other; in some, particularly among the Chinese, their direction is from top to bottom The Egyptian monumental writing, or hieroglyphics, is arranged in all these directions, and in several peculiar to itself. Sometimes we find it proceeding from right to left; sometimes from left to right; very frequently from top to bottom, in regular parallel columns; in a few instances, and but a spersed, as is usual in Asiatic cities, with gardens, burying- few, boustrophedon; occasionally arranged in groups or clusgrounds, and cultivated fields. Throughout the streets, ters, as in anaglyphs; and where the space was irregular

Book.

Book. as on the sides of obelisks, disposed in an arbitrary manner, varying according to the circumstances. But this total want of system, or rather this mode of arranging the characters upon all systems and in all ways, can never be productive of any difficulty or ambiguity, as the disposition and true sequence of the writing is in every case clearly and almost intuitively indicated by the direction given to the principal figures, more especially to those which represent animals, or the human form. With regard to the other modes of writing practised by the ancient Egyptians, that called the hieratic follows to a certain extent the varieties of the hieroglyphic; but the demotic, enchorial, or civil form, is generally disposed from right to left, in the ordinary manner of oriental writing.

Of the scarcity of books during the seventh and subsequent centuries Warton gives the following curious account: -" Towards the close of the seventh century," says this writer, "even in the papal library at Rome, the number of books was so inconsiderable, that Pope Saint Martin requested Sanctamund, bishop of Maestricht, if possible, to supply this defect from the remotest parts of Germany. In the year 855 Lupus, abbot of Ferrières, in France, sent two of his monks to Pope Benedict III. to beg a copy of Cicero de Oratore, and Quintilian's Institutes, and some other books: 'for,' says the abbot, 'although we have part of these books, yet there is no whole or complete copy of them in all France.' Albert, abbot of Gemblours, who with incredible labour and immense expense had collected a hundred volumes on theological, and fifty on profane subjects, imagined he had formed a splendid library. About the year 790 Charlemagne granted an unlimited right of hunting to the abbot and monks of Sithin, for making their gloves and girdles of the skins of the deer they killed, and covers for their books. We may imagine that these religious were more fond of hunting than reading. It is certain that they were obliged to hunt before they could read; and at least it is probable that, under these circumstances, and of such materials, they did not manufacture many volumes. At the beginning of the tenth century books were so scarce in Spain, that one and the same copy of the Bible, Saint Jerome's Epistles, and some volumes of ecclesiastical offices and martyrologies, often served several different monasteries. Among the constitutions given to the monks of England by Archbishop Lanfranc, in the year 1072, the following injunction occurs. At the beginning of Lent the librarian is ordered to deliver a book to each of the religious: a whole year was allowed for the perusal of this book, and at the returning Lent those monks who had neglected to read the books they had respectively received are commanded to prostrate themselves before the abbot, and to supplicate his indulgence. This regulation was partly occasioned by the low state of literature which Lanfranc found in the English monasteries. But at the same time it was a matter of necessity, and is in a great measure to be referred to the scarcity of copies of useful and suitable authors. In an inventory of the goods of John de Pontissara, bishop of Winchester, contained in his capital palace of Wulvesey, all the books which appear are nothing more than Septendecim species librorum de diversis scientiis. This was in the year 1294. The same prelate, in the year 1299, borrows of his cathedral convent of St Swithin at Winchester, Bibliam bene glossatam; that is, the Bible with marginal annotations, in two large folio volumes; but gives a bond for due return of the loan, drawn up with great solemnity. This Bible had been bequeathed to the convent the same year by Pontissara's predecessor, Bishop Nicholas de Ely; and in consideration of so important a bequest, that is, pro bona Biblia dicti episcopi bene glossata, and one hundred merks in money, the monks founded a daily mass for the soul of the donor. When a single book was bequeathed to a friend or relation, it was seldom without many restrictions and stipula-

tions. If any person gave a book to a religious house, he believed that so valuable a donation merited eternal salvation; and he offered it on the altar with great ceremony. The most formidable anathemas were peremptorily denounced against those who should dare to alienate a book presented to the cloister or library of a religious house. The prior and convent of Rochester declare that they will every year pronounce the irrevocable sentence of damnation on him who shall purloin or conceal a Latin translation of Aristotle's Physics, or even obliterate the title. Sometimes a book was given to a monastery on condition that the donor should have the use of it during his life; and sometimes to a private person, with the reservation that he who receives it should pray for the soul of his benefactor. The gift of a book to Lincoln Cathedral by Bishop Repingdon, in the year 1422, occurs in this form, and under these curious circumstances. The memorial is written in Latin with the bishop's own hand, which I will give in English, at the beginning of Peter's Breviary of the Bible. 'I Philip of Repyndon, late bishop of Lincoln, give this book, called Peter de Areolis, to the new library to be built within the church of Lincoln; reserving the use and possession of it to Richard Trysely, clerk, canon, and prebendary, of Miltoun, in fee, and to the term of his life; and afterwards to be given up and restored to the said library, or the keepers of the same. for the time being, faithfully, and without delay. Written with my own hand, A.D. 1422.' When a book was bought. the affair was of so much importance, that it was customary to assemble persons of consequence and character, and to make a formal record that they were present on this occasion. Among the royal manuscripts in the book of the Sentences of Peter Lombard, an archdeacon of Lincoln has left this entry: 'This book of the Sentences belongs to master Robert archdeacon of Lincoln, which he bought of Geoffrey the chaplain, brother of Henry vicar of Northelkington, in the presence of master Robert de Lee, master John of Lirling, Richard of Luda clerk, Richard the almoner, the said Henry the vicar, and his clerk, and others; and the said archdeacon gave the said book to God and St Oswald, and to Peter abbot of Barton, and the convent of Barden. disputed property of a book often occasioned the most violent altercations. Many claims appear to have been made to a manuscript of Matthew Paris, belonging to the last-mentioned library; in which John Russel, bishop of Lincoln, thus conditionally defends or explains his right of posses-'If this book can be proved to be or to have been the property of the exempt monastery of St Alban, in the diocese of Lincoln, I declare this to be my mind, that in that case I use it at present as a loan under favour of those monks who belong to the said monastery. Otherwise, according to the condition under which this book came into my possession, I will that it shall belong to the college of the blessed Winchester Mary at Oxford, of the foundation of William Wykham. Written with my own hand at Buckdane, 1st Jan. A.D. 1488. Jo. Lincoln. Whoever shall obliterate or destroy this writing, let him be anathema.' About the year 1225, Roger de Insula, dean of York, gave several Latin Bibles to the university of Oxford, with a condition that the students who perused them should deposit a cautionary pledge. The library of that university, before the year 1300, consisted only of a few tracts, chained or kept in chests in the choir of St Mary's church. In the year 1327 the scholars and citizens of Oxford assaulted and entirely pillaged the opulent Benedictine abbey of the neighbouring town of Abingdon. Among the books they found there were one hundred psalters, as many grayles, and forty missals, which undoubtedly belonged to the choir of the church; but besides these there were only twenty-two codices, which I interpret books on common subjects. And although the invention of paper at the close of the eleventh century contributed to multiply manuscripts, and consequently to facilitate know-

binding.

Books binding. ledge, yet, even so late as the reign of our Henry VI. we have discovered the following remarkable instance of the inconveniences and impediments to study which must have been produced by a scarcity of books. It is in the statutes of St Mary's College at Oxford, founded as a seminary to Oseney Abbey in the year 1446: 'Let no scholar occupy a book in the library above one hour, or two hours at most, so that others be hindered from the use of the same.' famous library established in the university of Oxford, by that munificent patron of literature Humphrey Duke of Gloucester, contained only 600 volumes. About the commencement of the fourteenth century there were only four classics in the royal library of Paris. These were one copy of Cicero, Ovid, Lucan, and Boethius. The rest were chiefly books of devotion, which included but few of the fathers; many treatises of astrology, geomancy, chiromancy, and medicine, originally written in Arabic, and translated into Latin or French; pandects, chronicles, and romances. This collection was principally made by Charles V., who began his reign in 1365. This monarch was passionately fond of reading; and it was the fashion to send him presents of books from every part of the kingdom of France. These he ordered to be elegantly transcribed and richly illuminated; and he placed them in a tower of the Louvre, from thence called La Tour de la Librairie. The whole consisted of 900 volumes. They were deposited in three chambers, which on this occasion were wainscotted with Irish oak, and ceiled with cypress curiously carved. The windows were of painted glass, fenced with iron bars and copper wire. The English became masters of Paris in the year 1425, on which event the Duke of Bedford, regent of France, sent the whole library, then consisting of only 853 volumes, and valued at 2223 livres, into England, where perhaps they became the groundwork of Duke Humphrey's library just mentioned. Even so late as the year 1471, when Louis XI. of France borrowed the works of the Arabian physician Rhases from the faculty of medicine at Paris, he not only deposited, by way of pledge, a quantity of valuable plate, but was obliged to procure a nobleman to join with him as surety in a deed. by which he bound himself to return it under a considerable forfeiture. Of the excessive prices of books in the middle ages there are numerous and curious proofs. I will mention a few only. In the year 1174, Walter, prior of St Swithin's at Winchester, afterwards elected abbot of Westminster, a writer in Latin of the lives of the bishops who were his patrons, purchased of the monks of Dorchester in Oxfordshire. Bede's Homilies and St Austin's Psalter, for twelve measures of barley, and a pall, on which was embroidered in silver the history of St Birinus converting a Saxon king. Among the royal manuscripts in the British Museum there is Comestor's Scholastic History in French, which, as it is recorded in a blank page at the beginning, was taken from the king of France at the battle of Poictiers; and being purchased by William Montague, Earl of Salisbury, for 100 marcs, was ordered to be sold by the last will of his Countess Elizabeth for forty livres. About the year 1400 a copy of John of Meun's Roman de la Roze, was sold at Paris for forty crowns, or L.33, 6s. 6d." (Warton's History of English Poetry, vol. i.) For further information regarding books, see BIBLIOGRAPHY

BOOKBINDING is the art of fastening together the sheets of paper composing a book, and inclosing them in cases of pasteboard covered with leather of various kinds, or other materials; the object of which is the preservation of the book, and its protection from injury while in use.

At the time when books were rarities,—either manuscripts produced by patient secluded labour, or the productions of the printing-press during the infancy of typography,—they were naturally very highly prized; and as much labour, skill, care, and expense were bestowed upon the protection and embellishment of a cherished folio as would suffice at the

present day to the building of a house. The wooden cover of a book, with its metal hinges, bosses, guards, and clasps, seems, in all but dimensions, fit for a church door; but since the great improvement in all the mechanical arts connected with the production of books, together with the extension of education to all classes, and the consequent diffusion of knowledge, literature has become almost as necessary as clothing and shelter to the comfort of civilized man; hence the multiplication of books, and the gradual but radical changes witnessed during the present century in the art of bookbinding. When libraries were comparatively of limited extent, large sums of money were expended upon binding; but, at the present day, when a well-selected library must of necessity be extensive, a substitute for the old method of binding is sought and obtained in the recent adoption of cloth covers.

As the binding of a book adds considerably to its cost, we find that in France, Germany, and other Continental countries, as well as in the United States of America, most books when first published are merely sewed together, and covered with a paper wrapper, like our magazines. In England, the now elegant and durable cloth binding presents so finished an appearance when ranged upon the shelves of a library, as to supersede the necessity of resorting to the style of binding so long prevalent. The libraries of the affluent, however, continue the demand for that durable and ornamental style of work which has continued in vogue, with slight variations, for the past century; and since all the essential features of other descriptions of binding are contained in this, we shall briefly describe the operations in the successive stages of binding a book, and afterwards indicate the variations included in the other kinds of binding.

The dimensions of the sheets of paper upon which a book is printed, together with the number of pages into which the sheet is divided, necessarily determine the size of a book; for instance, a sheet of the size known as foolscap may, according to the number of times it is folded, make a folio book, a quarto, or an octavo; and so with other sheets of different dimensions, such as demy, royal, imperial, &c. Previous to the present century, folios and quartos were the predominating sizes of library books; but, at the present time, the more portable and convenient octavo is preferred, generally the demy sheet folded into that form, making sixteen pages.

The sheets of a book are readily distinguished from each other by signatures at the foot of the first page of each sheet; and it is to these, and not to the paginal number, that the binder looks in arranging and collating. In foreign countries these signatures consist of consecutive numbers; while in this country alphabetical letters are adopted: we give the preference to the former, as being less productive of error in collation, and as possessing certain other advantages.

The operations of binding may be conveniently grouped under two main divisions—"forwarding" and "finishing." Under the first is comprehended everything necessary to the preservation of a book—the second concerns merely the embellishment.

In the first place, the sheets of a book are folded in such a manner that the pages follow each other in consecutive order. In this operation the binder is guided by the "signatures," which indicate the part of a sheet to be superimposed upon another. This labour is performed by women and girls, who acquire incredible dexterity by long-continued practice. The sheets, after being folded, are loose and bulky. The next operation has for its object the bringing them into a more compact form, which is accomplished either by beating them with a broad-faced hammer upon a smooth flat stone, or by passing them between the cylinders of a "rolling machine," invented for that purpose by Mr Burn of Hatton Garden, London. A book must not be submitted to the "beating" process until it has been printed one or two years; for the heat generated by the compression of the air under the blows of the hammer, causes the printing-ink to soften, and "set off" or transfer a portion of its substance to the opposite pages, by which the book is always disfigured, and frequently entirely ruined. This objection does not lie against the rolling machine, provided

Bookbinding. the cylinders are kept clean; while a great saving of time is effected by its use.

The next operation is that of sewing the sheets together, and to the bands of string or cord by which the book is sub-sequently secured in its case. The sheets being carefully collated, are given to the sewer, who sits before a contrivance called a "sewing machine," in which the bands are fixed at suitable distances apart: the number of these bands depends upon the size of the volume and the quality of the binding; six bands are usually allowed to folios, and five or four to quartos and octavos: the sewer places a folded sheet with its back to the bands, and pierces it through the middle fold with a needle carrying the thread, at distances corresponding to the bands. The thread, when passed through the sheet, is twisted round the contiguous band, and so with each in succession, until all the sheets composing the volume are fastened to the bands. This method involves what are termed raised bands, which are recognised by a projection over each on the back of the book; but if the back is required to be flat and smooth, sunk bands are adopted. To obtain these, the sheets, before being given to the sewer, are by means of a saw grooved at the back, sufficiently deep to admit the bands. If plates are to be inserted, they are either pasted in at the appropriate places, or, which is preferable, stitched through a marginal fold. When the is preferable, stitched through a marginal fold. book is released from the sewing machine, about half an inch of each band is left attached on either side: these ends are "frayed" out and beaten flat, to prevent their forming protuberances on the cover to which they are fastened; the "endpapers" intended to line the inside of the cases are now attached, and the back of the book is covered with glue. Before the glue is quite dry the back is rounded with a hammer, and subsequently placed between two feather-edged boards, above which the back of the book slightly projects; these are then placed together in a press, for the backing process; that is, the back of the book is well beaten until it projects a little over each side of the levelled boards, so as to form a groove or place for the millboard covers to lie in. The book is now removed to the "cutting-press," where, by means of an instrument termed a plough, the edges are smoothly cut; but, in order to preserve the concavity of the fore-edge, the back is temporarily flattened, and after the edges are cut, it is restored to its former roundness. The boards were formerly, as the name indicates, really of wood, but now of thick brown paper or millboard, of various thicknesses, according to the size of the book. They are cut a little larger than the book itself, and attached by the ends of the bands, left for that purpose, being passed through holes in the sides of the boards, glued down, and then hammered flat and smooth. The edges of the volume are now coloured, marbled, or gilt and burnished.

The head-band is an ornamental appendage employed for the purpose of concealing the leather folded over the back. It consists of a piece of parchment or card-board, worked over with coloured silk, which is sewed to the glued back of the sheets, and gives an elegant finish to that part of the book.

Sometimes books are preferred with hollow backs, that is, when the leather of the cover is not attached to the glued back, but this latter is covered with a piece of thick paper. The book is now ready to receive its external covering.

This external covering may be of various materials. For the most part of modern books it is of calf-skin dyed of various colours; but kid-skin, and its imitation in sheep-skin or roan, and sheep-skin acknowledged as such, in which school-books and many law-books are bound, are also used in great quantities. The piece of leather, cut to a proper size, is moistened with water, next covered on the inner side with paste or glue, and then applied evenly to the millboard sides; the superfluous edge of the leather, first pared to reduce its thickness, is turned over on the inside, and concealed from view by the end papers attached to the sheets forming the book, which are subsequently pasted down upon the millboards. The book is now "corded," that is, firmly tied between two boards until it is dry, so as to msure perfect smoothness in the cover; it is next removed from these boards and transferred to the finishers. Besides the "lettering" at the back of a book, there is generally a variety of ornamental work, on the back, edges, and sides, the patterns of which may be executed either in blind-tooling, wherein the leather is simply embossed, without the use of gold, leaf; or the metal may be applied only partially to the patterns, or they may be executed wholly in gold-leaf. This is a matter

affording much room for the display of taste and skill on the part of the binder, and in many instances is taken advantage of; by none more, at the present day, than by Mr James Hayday of London, whose productions fully equal those of the most eminent binders of past times. The embossing is performed with the aid of brass tools cut to various patterns; when leaf-gold is applied, it is made to adhere by moistening the leather with the glair of egg mixed with olive oil; the gold-leaf being laid upon this, the hot embossing tool is carefully applied, and the pattern permanently impressed upon the leather.

There are many other minute details into which it is not our purpose to enter. Enough has been said to indicate the various operations to which a book is submitted in being "bound;" but as good binding is necessarily expensive, those who have large libraries to bind are frequently obliged to study economy. This end is attained without in any degree sacrificing elegance of appearance, or any of the essential qualities of binding, by adopting the method of having the books half-bound, as it is termed. The only difference between this method and that just described consists in the sides of the millboards being covered with paper or cloth, while the back and corners of the cover are protected with leather: the edges of the leaves are often not cut on the front and bottom, but only on the top, which is usually gilt, to protect the book from disfiguration by dust.

The various styles of binding are distinguished from each other by appropriate names, according to the material which is used for the covers. Russia leather is much prized on account of its not being liable to mould in damp apartments, nor to the attacks of insects. These qualities, together with its agreeable odour. it derives from being treated with the empyreumatic oil of birch bark: its peculiar red colour is due chiefly to a dye of Saunders' wood. Many of the Continental books are bound in vellum, a very elegant but expensive style. In Holland and Spain much hog-skin was formerly used. Besides these various leathers, textile fabrics have at all periods been extensively employed for the purposes of binding; some specimens of the earliest dates are covered with velvet and satin; in recent times silk was in great demand for annuals and kindred works; but lately cotton cloth embossed and dyed has, in the extent of its applications, exceeded any other material ever employed. Previous to the year 1825, new books were generally published in boards; that is, millboards covered with drab paper, upon which the title, printed on a white label, was pasted. Although this was greatly superior to the Continental mode of covering new books with thin paper, something more elegant and durable was needed, and Mr Archibald Leighton of London endeavoured to meet this want by introducing coloured cloth (glazed calico). One of the first books of importance bound in this material was the edition of Lord Byron's works in 17 volumes.

Since that period there has been a progressive improvement in the adaptation of coloured cloth to the purposes of binding, both in the colours imparted to it, and in "embossing" upon its surface the grain peculiar to morocco and other kinds of leather; and so perfect is this imitation, that an experienced eye can scarcely detect the difference. The sides and backs of "cases" covered with this fabric are also ornamented in bold relief, with elegant patterns, by means of brass tools applied by powerful arming-presses; while the "lettering," at first so clumsily executed, is now as perfect as that impressed upon leather. Skilful artists are constantly employed in designing ornamental patterns; and a new class of tool-cutters, who cut these patterns in solid brass, has been called into existence. Expensive machines also for folding, pressing, cutting the edges, &c., have been contrived.

This style of binding has been received with so much favour that the rapidity of its extension is almost incredible. At one of the numerous large establishments in London, 310 persons are employed, distributed as follows:—200 women and girls are occupied in folding, collating, and sewing; and 110 men and boys in the more advanced stages: of these, 40 men are engaged in backing, cutting the edges, &c.; 5 in gilding or marbling the edges; 15 in making cases; 24 in stamping the sides; 12 as extra binders and finishers of the better kind of work: and 14 as clerks, porters, &c. Ten arming presses for stamping the sides of the covers, each worked by two men, will furnish 3000 impressions per day from a brass block "in blind," i.e. without gold leaf, or 1500 impressions if with the gold. The value of the gold leaf consumed amounts to L.4000 perannum. The superfluous gold wiped off the pattern is saved.

Bookbinding. Bookbinding. and sold for L.800 per annum. The quantity of millboards used is at the rate of 8 tons per month. Four men are constantly employed at as many cutting-machines, each of which yields a hundredweight of shavings per week. One man is employed solely in sawing the backs of books; two others in cutting millboard to the required sizes, and four pairs of men in making cloth cases, each pair producing on the average 1200 cases per diem.

The operations in the process of cloth-binding differ from those described under calf-binding in this,—the sheets are not beaten or rolled, nor the edges cut, except that the fore-edge and the tail are usually trimmed; the cases are made separately, and not fastened to the sheets by the bands, but only by the end papers, or by a strip of coarse muslin attached to the glued back of the sheets, being also fastened to the inside of the case. Cloth-covered books have always hollow backs.

There is a recent improvement in fastening together books of plates, music, account-books, &c., which are required to lie open flat; these are not sewed, but the back edge of the leaves is cut even, rasped, and cemented with liquid India-rubber.

The material with which books are covered should be selected with reference to the "tear and wear" to which they may be subjected. For public libraries, the very best workmanship in the forwarding should be secured, while the finishing bestowed must have reference to neatness and economy. The lettering of books rarely receives the consideration it demands; a simple rule is, that it should clearly indicate, 1. The author's name; 2. The subject, and even the divisions of a subject; so that the book may be identified without removing it from its place. In serial works, besides the consecutive number, the date should be affixed, and sometimes even the place of publication. These details may appear trifles, but whoever has to do with large libraries will appreciate their utility. If they are left to the discretion of the binder, he generally contents himself with lettering a book "History of Rome, "Travels in Europe," which obviously necessitates the opening of the volume before its individuality can be ascertained. For private libraries of large extent there is no better style of binding than "half morocco" with gilt tops, occasionally interspersed with specimens of other styles.

The classification of books in large libraries may be greatly facilitated by appropriating certain colours to specific subjects; e.g. theology might be clothed in black or dark purple; history in scarlet; poetry in light-blue or green. In this manner, and by combining them with coloured labels of various hues, the labour of sorting and replacing books upon the shelves may be much lightened to the librarian.

Bookbinding still lacks its historian: it is much to be regretted that on a subject so well deserving the attention of the curious and learned, no researches have been made into the origin, progress, and decline of this art. Beyond a few incidental and fragmentary passages in the writings of bibliographers and travellers, merely descriptive, we may seek in vain for reliable information. In this place we have endeavoured to collect the scattered materials, and present them in a concise form.

Although it is customary to refer binding to remote antiquity, it obviously could not have been practised before books assumed their present form. The manuscripts of the ancients consisted of continuous rolls of papyrus or parchment, a form which did not admit of being bound like the single leaves of a modern book. These manuscripts were wound upon rollers, as our maps are mounted, to which labels bearing the titles were attached at the ends: these rolls were inserted in parchment cases, and preserved from dust and injury in cylindrical boxes with lids (see Gell's Pompeii, &c.) It is more probable, however, that the modern book derived its form from the means taken to

preserve the waxed tablets of the Greeks and Romans which were inclosed in covers of wood, ivory, &c. (diptycha, triptycha). It would be easy to substitute pieces of papyrus or parchment for these pieces of waxed wood, upon which the writing was graven by the stilus. These diptycha were frequently elaborately carved and ornamented, and many of them, preserved to the present time, very nearly resemble our modern octavos in size. When parchment came to be exclusively employed as a writing material, it gave rise to the invention of libri plicatiles and volumina, names which very clearly indicate the form given to manuscripts. The volumen, so called a volvendo, was the form mostly employed with papyrus and parchment, and now that our books are square or oblong, the term is anomalous; the word remains, but the thing itself has long since entirely disappeared.

binding.

It would be exceedingly difficult to determine what the art of bookbinding, or that which occupied its place, was during the middle ages, as no evidence remains, and the light of discovery has not been thrown upon it. All that we can at present learn is, that in the ninth and tenth centuries, owing probably to the impulse given to letters, and to everything connected with literature, by Charlemagne and the princes of his line, the external decoration of manuscripts was carried to a high state of perfection. The parchment, in leaves, was inclosed between two tablets of wood or ivory, inlaid and incrusted with jewels and precious stones, bosses of gold and silver, sometimes with hinges and clasps of these metals. The Bibliothèque Impériale at Paris is very rich in this description of bindings.

The library of the Louvre contains the celebrated Book of Hours, written with letters of gold upon purple parchment: it is covered with red velvet. This book was given to the city of Toulouse by Charlemagne. A New Testament of the eighth century, bound in wooden covers, covered with black satin, in an excellent state of preservation, enriches a private collection.

It was probably only at the epoch of the invention of paper from rags, and its extended use, that modern binding arose: this was towards the end of the thirteenth century (1280). From this period to the sixteenth century the bindings are numerous, but no name of a binder has reached us; they generally followed the good or bad taste that prevailed at the time in other ornamental arts. Thus, during the fifteenth century, binding, like architecture and the ornamental letters of MSS., abounded in foliages and flowers (arabesque), but at no period do we find the elegant simplicity that prevailed in the arts at the commencement of the fourteenth century. The most beautiful bindings preserved to us of the fifteenth century are those of the famous library formed at Buda by Matthias Hunyadi, king of Hungary; it consisted of nearly 50,000 volumes of Greek and Latin manuscripts. They are but very little known. The greater portion of the treasures of this sort collected by Matthias are now in the public library at Munich.

Apart from mere decoration, the main object aimed at in the early bindings was strength and durability, and whether it was owing to the binders being fettered in their ideas to the ivory or wooden covers of the tablets they first imitated, or from an excess of care in securing the preservation of the treasure they inclosed, it is certain they laboured overmuch in their vocation. A folio of this era, with its timber and metal, must have been a formidable affair; and the very means employed for the preservation of the book doubtless frequently led to its destruction.²

1 The oft-repeated encodes which attributes the erection of a statue to Phillatius, an Athenian, for the invention of bookbinding, is evidently founded upon a misconception of the text of Photius; all that the Athenian did was to glue together into one continuous roll (volumen) the pieces of papyrus, which were previously sewed together.

In the Laurentian Library at Florence is Petrarch's manuscript of Cicero's Epistolæ ad Atticum, remarkable for its calligraphy and workmanship. The binding is only of the time of Cosmo. The old wooden covers of this volume, so often handled by the poet, had so wounded him by falling repeatedly on his left leg, that he narrowly escaped amputation. So rude and almost murderous were literary pursuits at that period. This volume has still, as before, brass clasps and corners, but they would not inflict such a wound.—Valery.

Book-

The sixteenth century, the epoch of the Renaissance. keeping. is doubtless that in which the art of binding attained its greatest perfection, and the books extant in various public and private libraries confirm this view. It would be out of place to enumerate these treasures, but it would be difficult to meet with one more beautiful than that of the Hours of Margaret of Savoy. At the court of France, during the time of Catherine de' Medicis, there was a perfect rage for ornamental binding, its greatest promoters being Diana of Poictiers, the treasurer Grollier, the presicent De Thou, and M. d'Urfé.

In the seventeenth century, with the exception of the bindings executed by Ruette, bookseller and binder to Louis XIV., the art at first remained quite stationary, and afterwards quickly declined; the intrigues and troubles of this period were by no means favourable to so innocent and harmless a passion as that for choice bindings. The eighteenth century was, however, more congenial; the names of eminent binders are sufficiently numerous to indicate that their vocation was in the ascendant. We can only enumerate Enguerrand, Boyer, Desseuille, Padeloup, Gascon, Derôme, Chameau, Pontchartrain, Simier, father and son, Purgold, Vaugelles, and Bauzérian. Bauzonnet was cotemporary with our Lewis. Upon the whole, the bindings of France excel those of any other nation; they always exhibit a refined taste, and perfect manipulation in the tooling. At the present day the best designs are generally but close imitations of the productions of the past.

The most eminent cotemporary binders of France are Madame Gruel, MM. Niédrée, Lortic, Simier, Cape, and keeping.

The earliest ornamental binding extant in England is of the time of Henry VII.; many specimens of this period are preserved in the British Museum and the Record Office. Stamping the covers with brass tools appears to have been first practised in the reign of Henry VIII., many of which are supposed, upon what authority we know not, to have been designed by Holbein. In the reign of Elizabeth velvet covers embroidered with gold and silver thread and coloured silk were fashionable. It was only in the eighteenth century that binding assumed importance as an art in Eng-The first, and still unsurpassed binder, is Roger Payne, who was so completely the founder of his art, that he performed every operation with his own hands, from folding, beating, sewing, cutting, mending, head banding, colouring his end-papers, covering, tooling, even to the cutting of the brass tools and letters. The other eminent names since his time are Johnson, Lewis, Kalthoeber, Baumgarten, Bohn, Staggemeir-the last four being Germans; Mackenzie, Clarke, Bedford, Jones, Hering, Hayday, Wright, Rivière. In the present day we have produced no original style of decoration for leather-binding; our highest achievements are in imitating the productions of past centuries. When these imitations combine good taste with good workmanship the highest aim of binding is accomplished, until a new style is origi-(C. M-L.)

BOOK-KEEPING.

BOOK-KEEPING is the art of keeping books of account, whether in public offices, manufacturing establishments, or mercantile counting-houses; but the name is generally applied to the books of merchants, on account of the complexity of their transactions, and the care consequently required to prevent obscurity or confusion. It was accordingly among merchants, and in particular among those of Venice, Genoa, Pisa, and other trading towns in Modern Italy, that book-keeping was first reduced to a system, and that the remarkable refinement of double entry was adopted. This, like the discoveries of the Italians in manufactures, the fine arts, navigation, and commerce, was owing, not, as some imagine, to any peculiarity of disposition, or power of invention, inherent in that people, but to their country being the part of Europe in which, in modern times, townpopulation first became considerable, and men derived advantage from living together in large communities. It is in populous towns that employment is divided and subdivided; that discoveries and inventions take place; and that the education of youth exchanges its antiquated and scholastic form for one of direct utility, adapted to the progress and the wants of the existing generation.

The first printed work on book-keeping was the production of an Italian teacher, who, without knowing much of trade by his own experience, observed the manner in which the intelligent merchants of his country kept their accounts. It was published as early as 1495, and was followed in the succeeding century by several works on book-keeping in French, composed with evident care and solicitude to explain the art, but affording by their complexity a remarkable contrast to the short and clear system afterwards adopted by merchants. English publications on book-keeping came forth somewhat later, but all resembled the foreign treatises in being the composition, not of merchants, but of teachers and accountants. In 1652 Collins, a well-known London accountant, published a long work entitled An Introduction to Merchants' Accounts, which, like the work of one of his contemporaries on a very different topic (Rich On Short Hand), continued during a century the best, or, to speak more correctly, the least imperfect publication on the subject of which it treated. About a hundred years later, Mair, a well-known writer of books on education, pub-

lished his Book-Keeping Modernized, a work containing a correct statement of the principles of double entry, but in other respects much less clear and concise than it might have been had the author adopted the method of our principal merchants, who had now greatly simplified their plan of keep-

ing accounts.
In 1789 appeared the work of a practical merchant, under the title of A Complete System of Book-Keeping, by Benjamin

Booth, London, 4to.

The favourable expectation excited by Mr Booth's experience in business was fully confirmed by his book, which contained a great deal of information in short compass, unembarrassed either by minute detail or fanciful theory. The plan which he recommended and exemplified was the Italian method of double entry, in conformity with the practice of the first merchants in this country and the Continent, for more than a century. Practical men could no longer complain of the nonexistence of a correct summary of the principles and practice of book-keeping; and the Italian method seemed likely to be as firmly fixed in the admiration of our young merchants as it had long been in that of their predecessors, when its title to clearness and accuracy was strongly called in question by a writer at that time unknown to the mercantile public.

Mr Edward Thomas Jones, an accountant in Bristol, had occasion, like Mr Booth, to see a series of perplexities and losses arising from books being badly kept, namely, disputed accounts, actions at law, and occasionally even bankruptcies. In the case of many merchants the books submitted to him had remained for years unbalanced; in others the balancing had been incorrect, and deception had been practised either on a partner or the creditors. Such irregularities, ascribed by Mr Booth wholly to the misconduct of book-keepers, is charged by Mr Jones on the system itself, which (the Italian method) he does not scruple to describe as "insufficient to prevent or detect error, rendering the process of balancing very difficult, and not necessarily correct when the balance is completed." To find a safeguard against such errors, to devise a method by which accuracy in book-keeping might be insured, and the perplexity in balancing removed, was, said Mr Jones, a work of great time and difficulty. He began to give his plan to the public in 1796, and improved on it in the succeeding years. He published a treatise on this subject in 1821, and again in a much more extended form in 1831. Of this work we shall

Book- treat more fully in the subsequent part of the present article, keeping. after explaining to our readers the nature of the system in

> In the earlier stages of commerce, such as the fifteenth and sixteenth centuries were for the north of Italy, and the seventeenth for England, the transactions of merchants, though varied in their nature, were on a small scale as regarded any particular department. The same individual did business in a number of articles, but in none to an extent to require separate books of account. Hence the practice of recording all transactions, whether purchases, sales, receipts, or payments, in a diary, which, from the rough manner in which it was kept, was commonly called a waste-book. The practice in those days was for a merchant or his chief clerk, as soon as any transaction was made or agreed on, to insert a memorandum taking little trouble as to the form of the entry: for that they relied on the book-keeper, who was not then a partner, or even clerk in the house, but generally gave his aid by intervals in different counting-houses, passing one or two days in the week at each, and bringing the rude entries in their waste-books into regular form in the journal. At present, and for a great length of time, each

mercantile house has its own book-keeper; the art being simplified so as to be within the attainment of most clerks of ability, instead of being, as in remote times, a mystery to all except men of long standing and more than usual instruction. But in process of time, as mercantile concerns have acquired extension, the art of book-keeping has been simplified, because particular departments of business have required separate books. Thus money receipts and payments, instead of being mixed, in the waste-book, with the amount of invoices, account sales, and other entries quite different in their nature, are all registered in the cash-book, or book for that special purpose. The same principle of division holds in regard to bills; also as to invoices, account sales, and, in short, every department of business.

We shall now give a practical illustration of book-keepof it in this book, minuting the particulars correctly, but ing, by exhibiting the course followed by a mercantile establishment. Let the example to be given be a London house under the supposed firm of Baring, Hall, & Co., established during several years, and engaged in the West India and North American trade. Their journal ought to contain, at the beginning of each year, a summary of the monies owing by and to them; in other words, of their debts and assets, in the following form.

Folio of Ledger.	January 1, 1831. SUNDRIES Drs. to STOCK.

--	--	--	---------------------------	---

Such is the form of the inventory of the debts and cent. interest, would in general be fruitless; but the case Bookmust be admitted, much more satisfactory than balance sheets in general; because, from the nature of foreign business, the funds of almost every house become unavoidably much more scattered than is stated in this outline. All countries recently settled, such as North America and the West Indies, are bare of capital, and have an interest in drawing money from Europe. This they have found it practicable to do to a great extent from England and Holland, where money is in general abundant, and the rate of interest low. In recently settled countries there generally prevails a spirit of adventure, a strong desire to extend their undertakings; hence a high interest for money, and sometimes little scruple as to the means of obtaining it. To apply to a merchant in London or Amsterdam for a loan of L.2000, for a year, at five per rally dependent on those of his customers.

assets of a mercantile house; and the foregoing is, it is different when the correspondent abroad holds out the keeping. tempting prospect of selling manufactures to the amount of L.2000, and remitting for them in cotton, tobacco, or sugar. Such a transaction offers a double commission, viz. 5 per cent. on the amount exported, and 2½ per cent. on the amount received in return; advantages which incline a merchant, in particular a young merchant, to take a favourable view of the chances of the proposition. The usual result, however, is, that the balance sheet of a house in such a line of business generally exhibits a long list of debts on the part of correspondents abroad, the recovery of which is more or less doubtful according to the prudence, integrity, or health of the debtor, or according to the degree of prosperity in the country of his residence; for, being obliged to sell on credit, his means are gene-

THE CASH-BOOK .-- Of the entries for the various receipts and payments which daily occur in a counting-house, the following is a specimen:-

Book-

These entries, few as they are in number, suffice to conkeeping. vey an idea of the advantage of putting them in the journal form. There are, in most of the preceding, two transactions belonging to each account, and these two are merged in the journal in one entry, which abridges and simplifies the posting in the ledger. But in houses of extensive business the cash transactions for a month are as ten, or rather as twenty to one compared to the preceding specimen, and the number of entries collected under one title, such as bills receivable or bills payable for the month, is consequently large. The result is to facilitate greatly the posting in the ledger, and of course the balancing of the books at the end of six or twelve months.

What, it may be asked, is the rule for making cash debtor in Booksome cases and creditor in others? The rule is clear and uni- keeping. form. For all monies received cash is made debtor, or accountable, as these sums are to be accounted for under the head of cash; while for all monies paid, cash is made creditor, the parties who have to account for the sum being made debtors.

BILL BOOKS.—Next in importance to the cash are the bill transactions of a mercantile house, whether bills receivable or drafts on other merchants, or bills payable, meaning by the latter the acceptances or bills which the house are bound to pay. For each is appropriated a separate book, in which the respective bills are entered, with a minute notice of particulars, thus:

	BILLS RECEIVABLE. Form of Entry.									
No.	Received.	From whom.	Drawn by	Date.	Term.	Drawn on	To order of	Due.	Sum	How disposed of
152	12 do.	T. Story & Co.	Jas. Wilson	Dublin, 20 Jan. Liverpool, 2 Feb. Jamaica, 8 Feb.	l do. 60 days' sight.	T. Gray J. Allan	John Smith	5 do. 14 May	232 0 0	Smith, Payne, & Smiths Overend & Co. Kept till due

The preceding bills are to be entered in the Journal as follows:

Ledger Folio.	BILLS RECEIVABLE Dr. to SUNDRIES.			
	For the following bills remitted.			1
10	To James Anderson.	L. 173	s.	d.
	No. 151, on J. Greig, due 23d March	173	10	0

		L.720	0	0

Bills of Exchange were introduced several centuries ago to enable merchants to make payments to each other without the risk and delay attendant on transmitting the precious metals to a distance. A, a merchant in Liverpool, Dublin, or in Jamaica, having a payment to make in London, instead of collecting and forwarding specie, looks out on his own exchange until he find another merchant, B, who having money to receive in London, is inclined to give him an order to obtain it in his stead. They discuss the terms or rate of exchange; and when these are agreed on, the bill is drawn by B and delivered to A, who then, or soon after, pays the amount to B. The result is, that the one acquits his debt in London, and the other draws

his funds from it, without quitting their place of residence or incurring any expense of consequence.

Bills of Exchange first became general in the middle ages, and were used chiefly by Jews. In the case of this, as of many other discoveries, the time and manner of their introduction is uncertain; but the accommodation from them must have been so great, and the mode of obtaining it so obvious, that we may safely take it for granted that they were adopted as soon as merchants accounted each other trust-worthy, or the transactions of towns at a distance from each other became such as to supply sums of any considerable amount to be drawn for.

Town Notes are bills drawn by persons residing in the

Bookkeeping.

India merchant in London on a sugar refiner, for sugar sold by the former to the latter; or by a wholesale warehouseman on a West India merchant for linen or cottons supplied to the merchant. It is evident that bills between parties residing in the same town are not strictly en regle, as in their case there can be no expense or risk in forwarding money. Still they can hardly be objected to in transactions like the preceding, which are evidently bona fide from the respective lines of business of the parties. The Bank of England sanctions town notes as regards the metropolis, by appropriating a day in each week (Wednesday) for discounting them, and by often carrying such discounts to a very large amount. During the war, when monied capital was comparatively scarce, town notes were extremely common. They are still very frequent, but not in so great a degree, first-rate houses being unwilling to give their acceptances where a payment in cash is the regular mode of settling an account. This feeling differs according to the line of business of the parties. Thus, London houses in the East India trade being generally large establishments, confine their acceptances to bills from abroad, and decline giving them to persons in London, such as the wholesale dealers in cloth or hardware, from whom they purchase goods for shipment. They prefer paying such persons in cash, even when not altogether convenient, to the animadversions that might attend their affixing their acceptance to a town note. On the other hand, London booksellers, though often possessed of considerable capital, are obliged, by the nature of their business, to give such long credits, that the postponement of a payment during several months, obtained by giving their acceptance, is an accommodation they readily en.brace. Besides, the custom of the trade, in this as in various other lines of business, prevents such acceptances from being an object of much animadversion.

THE INVOICE BOOK. A mercantile house connected, as we have supposed, with North America and the West Indies, receives from time to time requisitions, or, as they are commonly termed, orders, from their correspondents abroad for manufactured goods, whether woollens, linens, cottons, or hardware. An order of only moderate amount is generally of the length of several pages, embracing both

same town with the acceptors, generally by the seller of goods on the purchaser, who, instead of paying for them in cash, gives his acceptance, payable in two, three, or more months after date. Take, for example, the draft of a West India merchant in London on a sugar refiner, for sugar sold by the former to the latter; or by a wholesale ware-houseman on a West India merchant for linen or cottons supplied to the merchant. It is evident that bills between parties residing in the same town are not strictly en regle,

ACCOUNT OF SALES.—Having seen in the invoice a specimen of the mode of conducting our exports, we are now to show the manner of disposing of our imports. While our exports are generally in manufactures, our imports are commonly in raw produce, because, except in silks, and a few petty articles of manufacture, foreigners are quite unequal to a competition with the capital and

machinery of this country. Cotton, sugar, coffee, rice, idigo, form the main articles of import to England from tropical latitudes; while wine, brandy, olives, drugs, are sent to us from temperate climates; and corn, timber, hemp, flax, tallow, hides, reach us in large quantities from the Baltic. We shall take, as an example, an account sale of the staple article of our West India colonies.

Book. keeping.

We have now given examples of journal entries from the parties, to put them away in bundles. But the prethe principal books in a counting-house; from the cash- ferable plan, wherever such accounts are numerous, is, keeping. book, the invoice and account sales book, as well as from after arranging them alphabetically, to have them pasted the bills payable and receivable. After these comes the in a large quarto or folio volume of blue or sugar-loaf petty journal or record of such occasional entries as do not belong to the preceding, or any other subsidiary books. Such entries are in general very few, because, in every regular counting-house, the subsidiary books contain almost every transaction that takes place.

Insurances.—It is customary to have an insurance policy book, a folio book of the length and breadth of a printed policy, and containing a quantity of such policies bound up, unstamped. In these are filled in, by a clerk, literal copies of the insurances effected by the house, with the names of the underwriters, and the amount of their respective subscriptions. From this is posted the insurance ledger, containing the accounts of the underwriters for and other small matters; the amount is entered weekly premiums and returns.

Bought Book, or Book of Bills of Parcels.—In former times, when mercantile transactions were on a limited scale, the practice of a merchant, as of private individuals at present, was merely to fold up the bills of parcels, or accounts delivered to him by dealers, in a uniform size, and, after writing on the back the names of spective heads in the ledger.

paper. A surprising number of accounts may be contained in one of these books; and its pages being numbered, any account may, by the aid of an alphabetical index, be referred to with the same ease as an entry in a

Drawbacks payable at the custom-house on goods exported, and for which the merchant holds a debenture or acknowledgment of debt on the part of the custom-house. Of these a list or register should be kept, either in a small separate book, called the debenture book, or in a specific part of one of the larger books.

The petty cash-book contains the disburse for postages

or monthly in the regular cash-books.

We have now recapitulated the various subsidiary books which form the groundwork or authorities for the journal. The ledger comes next, and by way of affording a specimen of this, the finale of book-keeping labour, we shall exhibit the preceding journal entries, carried to their re-

LEDGER.

Bookkeeping.

The entries in the ledger are very concise, containing ference is sometimes very small; a few pounds, a few shilgenerally nothing more than the head or title of the entry in the journal to which they refer. It was formerly the practice of book-keepers to insert some explanatory words in almost every line: thus under profit and loss, instead of such short notices as

January. By Cash......L.14 14 0

October. By Sugar per Andromeda...17 0 0 a book-keeper in a former age would have thought it necessary to write

Jan. By Cash received for sundry discounts...L.14 14 0 Feb. By A. Dixon & Co. commission on goods

Oct. By Sugar per Andromeda, commission

on insurance and sale.......17 0 Such explanations are not without their use, as by means of them a person looking over the account is quickly informed of the nature of the different entries. They may therefore be inserted wherever the business is on a small scale, because in such a case they do not add much to the labour of the book-keeper; but wherever the business is extensive, all detail in the ledger ought to be avoided, and the entries made in the most concise form possible, for the following reasons.

tial as to supersede the necessity of an account-current

2. Nor can they supersede a reference to the journal in what may be called collective entries, such, we mean, as the bills payable discharged, or the bills receivable encashed, in a particular month; entries in which a number of particulars are collected in the journal, and carried to the ledger in one sum. And,

3. It is desirable to have as many of such collective entries as possible, limiting thereby the number of postings in the ledger, and lessening the difficulty of balancing it at the end of the year. Such was the recommendation of Mr Benjamin Booth, in his printed work, more than half a century ago; and such had long before been the practice of our best merchants.

It follows therefore that the ledger ought to be merely an index to the journal, exactly as the journal is an index to the various subsidiary books of the house. To aim at more, and to repeat in any one of these books statements or particulars already contained in the other, would be quite a work of supererogation.

Balancing the Ledger.—At the end of each year, and, in some houses, of each half year, the ledger is balanced; that is, the debtor and creditor side of each account in the ledger is added up, and the balance or difference entered in a general list or balance-sheet. Thus a few accounts taken from the preceding fragment of a ledger exhibit the following balances:-

Debtors. Creditors. J. Anderson & Co. L. 1849 3 0 Bills Payable.....L. 4972 5 0 Thos. Story & Co. 796 11 0 Gregg & Lindsay 498 10 0

The balance-sheet is generally very long, comprising on one side or the other every open or unclosed account in the ledger. The rule in all regular counting houses is to make the sum of the debtors in the balance-sheet correspond with the sum of the creditors, and to spare no pains to accomplish such agreement, because until it be done there must evidently be an error in some part or other of the journal or ledger. Unluckily, the amount of the difference gives almost no clue towards tracing either how it has taken place, or the part of the journal or ledger where it is to be looked for: it may be in any day of the year, or in any of the entries (1000, 2000, or perhaps 3000) which the ledger for the year contains. The dif-

lings, or a few pence; but the fractional errors are often as difficult to detect as a large sum; and in fact it is not unfrequent, in the process of examining, to discover new errors, which, instead of diminishing, add to the amount of the existing difference, carrying it from L.10 to L.100, or even to L.1000. Hence the necessity of experience and habitual accuracy in a book-keeper. To one deficient in these respects balancing a ledger of length is generally a most laborious and tedious task, requiring week after week to be passed in the dry labour of collating, adding, and subtracting. Mr Jones' method will, it is to be hoped, be the means of preventing the continuance of these unprofitable searches; for we are satisfied that the labour given to the precautionary arrangements recommended by him will be saved, and doubly saved, in the final winding up of the books.

We have already adverted to Mr Jones's first publication on book-keeping; his second, in 1821, was intended to counteract the inconvenience attendant on the form of his ledger, which required that the accounts should be opened anew each year. His third and most important work, published in 1831, is of a much more comprehensive character, and may be said to exhibit the result of more than thirty years' experience as a public accountant. It is printed in the quarto form, and consists of a number 1. The explanations never can be so full and circumstan- of distinct parts; first, explanatory statements of his mode of book-keeping by single as well as double entry, with a number of formulæ, in which the same transactions are exhibited by the Italian and by his method, so as to bring into view the various advantages of the latter. These are followed by a series of instruction to persons in different branches of business, viz. bankers, manufacturers, brokers, wholesale and retail dealers, in regard to the books of account best fitted to their respective occupations; the whole followed by a treatise in the form best adapted to the government offices. Such are the contents of the first or printed half of Mr Jones's book; the other half is lithographed, and exhibits two sets of books, each for a year, one kept by single, the other by double entry. Along with these are given a balance-book and an abstract-book, devised for the purpose of leading promptly to the detection of errors or false entries. This they will fully accomplish if the plan laid down by Mr Jones is carried into effect; and they seem to us also well calculated to save the perplexity and loss of time at present so often incurred in efforts to find the general balance. The Italian method, ingenious as it was, and a surprising improvement at the time on the primitive system of single entry, is not an effectual preventive of erroneous or fraudulent insertions in the books; nor does it present any ready method to facilitate the laborious task of balancing the ledger. It is consequently the practice of Messrs Barings, and several mercantile houses of the first rank, to keep two sets of books as a check on each other; but the object of Mr Jones is to attain correctness in the first instance, by submitting to some extra trouble as the posting of the books proceed. Thus, his abstract-book is a classed epitome of his journal, and forms the first check against posting entries to wrong accounts; while his balance-book is an epitome of the ledger, and forms another check, both against carrying entries to a wrong head, and making a mistake in the figures so carried. In many counting-houses the uncertainty of the Italian method is counteracted by habitual accuracy in the book-keeper; but Mr Jones's auxiliary books are devised with the view of enabling even a mediocre book-keeper to avoid mistakes, or to detect them soon after they are made. By means of these books he may prove his ledger not only in any month, but in any week, or even in any day, of the year.

Nothing is more desirable than frequent balancing of

counts to his connections. A year is evidently too long dered to persons in trade.1 for accounts-current to remain open; to settle every six described have the effect of lessening the difficulty of ge- accounts; thus,-

the books of a merchant, and frequent transmission of ac-neral balances, an important service will thereby be ren-

An index is indispensable to a ledger, but it ought to be months is more suitable; and if the improvements we have very short and plain, containing merely the titles of the

keeping.

remaining in use. The latter has the advantage of showing the transactions of a long period in succession, as well as of saving the repeated opening of the same accounts.

The stock account has no entries during the currency of the year, but at its close (on 31st December) the balances of profit and loss, bad and doubtful debts, and a few such accounts, are carried, as the case may be, to its debit

Collective Entries in the Journal.—It may be proper to explain what is meant by such entries in the journal. While in the bill-books every bill is entered the day it comes to hand, and in the cash-book every payment or receipt is entered on the day it takes place, the journal entries are made to comprise in one amount a number of transactions occurring at different dates in the course of the month. Thus the entry of "Sundries Drs. to Bills Payable" exhibit in succession all the bills accepted during the month; they are then added in one sum, which sum alone is carried to the ledger. In like manner, in the entry of "Bills Receivable Drs. to Sundries," the aggregate alone is posted in the ledger; and the same in a variety of cases, the effect of which is to lessen greatly the difficulty of agreeing the books at the end of the year. We cannot, therefore, approve of the practice of those book-keepers who, to save themselves the trouble of re-writing the cash-

Size of the Ledger .- In some houses of very extensive book in the journal form, are content to post each separate business the rule is to have a new ledger for every year; sum directly from the cash-book to the ledger. They thus but three or four years are the more usual time of a ledger avoid, it is true, the copying of eight or ten folio pages a month; but by giving up the advantage of joining in one sum the different payments made under such heads as bills payable, charges, house expenses, they have to carry to the ledger during the month above 100 entries instead of perhaps only thirty or forty.

The Waste-Book.—This book has long been disused by regular merchants, and the name itself would have been forgotten, had it not been reprinted from one work on bookkeeping to another, the authors of which, being generally teachers, were unacquainted with the improvements introduced into the practice of merchants. The wastebook of former times consisted of a series of memoranda, so miscellaneous as to comprehend every transaction of the house, whether a sale, a purchase, a payment, or a receipt. From this general receptacle the book-keeper composed the journal, which was then, as at present, a narrative or record, in regular form, of the transactions of the house. As mercantile establishments acquired extension, separate books became necessary, as well for the cash and bills as for goods exported and imported. These books were found the fittest authorities for the journal, and the waste-book or diary fell altogether into disuse.

Single Entry.—A wholesale dealer occupying a warehouse, and whose business consists in supplying such articles as woollen, cotton, linen, or hardware, to exporting

merchants, is generally satisfied with few books. He is a large sum may be vested in machinery, shipping, or Bookaccustomed to enter each delivery of goods in his day parcels made out for his customers, of which examples have been given above in the names of Balmanno and Oakey & Company. He seldom keeps a journal, but a ledger is indispensable, though not kept by double entry. It consists on one part of the names of his customers (the exporting merchants), and, on the other, of those of the manufacturers from whom he makes his purchases. From the latter he receives credit, and to the former he gives it; hence the necessity of opening accounts for both. At the end of the year, a person in such a line of business is accustomed to form an estimate of the state of his affairs by adding up on one side the sums due by him to the manufacturers, and on the other those due to him by the merchants. He takes, moreover, an account of his stock, or goods in hand, which being valued, and the amount added to the sums due to him, the difference between their conjunct amount and the total of his debts affords a tolerably correct idea of the state of his property. It would, however, be much more clear and satisfactory were his books kept by double entry, that is, were every debtor to have a creditor, or, in other words, were every entry to have its counterpart. Suppose him, for example, to make a purchase from Messrs Greenup of Halifax, for L.1250 of the coarse woollens called penistones, he merely enters in his ledger that sum to the credit of Messrs Greenup; but the proper course would be to find a debtor for the same amount by such an entry as "Penistones Dr. to Messrs Greenup, L1250." Subsequently, on effecting sales of the article to exporting merchants, the proper course would be to make entries such as " Baring, Hall, & Co. Drs. to Penistones for L.225;" and by continuing such entries, that is, by crediting the account of Penistones for the sales as successively made, until the whole was disposed of, the ultimate result would be that the creditor side would exhibit a total equal to the L.1250 paid to Messrs Greenup, and to the profit accruing from the transaction.

Double Entry has farther and more important advantages to a merchant than to a tradesman, because his dealings are much more varied and complicated. It forms the connecting link of his accounts, and shows in what manner in his books has a creditor, no part of his property is unaccounted for; and when in doubt as to any specific portion, he will find a solution of the difficulty in his own journal. Those who know how soon money becomes absorbed, or at least appropriated in business, and in how few years twelve months; thus-

other fixed capital, are aware that merchants would often keeping. book, and to get copied into his invoice-book the bills of consider themselves deceived, if they had not in double entry an unfailing clue to the appropriation of their capital.

> Next, as to the degree of intricacy in double entry. In the case of a shipment of goods, the merchant abroad who receives the goods is made debtor to the several dealers at home who have supplied them; e. g. A. Dixon & Co. of New York are Drs. to Spitta & Co., Jobson & Co., &c. In like manner, in the case of produce imported, the brokers, Trueman & Cook, who sell it and receive the amount, are made debtors to Simon Fraser, for whose account the produce was shipped. All this is clear and free from intricacy, as also such farther entries as Cash Dr. to Trueman & Cook, on their paying over the proceeds of the sale, or Bills Receivable Drs. to A. Dixon & Co., on their remitting or sending home a bill for the amount of the goods forwarded to them. It is true that a young merchant beginning to study book-keeping will not all at once comprehend such an account as Bills Receivable, nor its counterpart Bills Payable, nor a few other accounts, such as Charges and Merchandise; but practice will convey a distinct conception of them, and render them in time as clear as personal accounts.

> The advantages of double entry may fortunately be imparted to almost any account-books, without sacrificing much time and labour. Persons engaged in such business as that of wholesale warehousemen, manufacturers, or retailers, may keep the chief part of their books by single entry, making use of double entry to the extent of a few pages at the end of the month or quarter, to obtain a clear and summary view of their transactions.

> As to the money or currency in which the books of a merchant should be kept, it is evident, first, that it can be money of one kind only; and, next, that it must be the money of the country in which the merchant resides. Thus, an English house in Bordeaux must keep its accounts in French money, although its chief business may be the export of wines to London and Dublin.

We come, in the last place, to Accounts-current, which, though a most important portion of the accounts of a merchant, are rather the result than a constituent part of his system of book-keeping, being in general written out from his funds have been successively invested. As every debtor the ledger and journal, with very slight variation or addi-Accounts-current are prepared for transmission to the correspondents whose names they respectively bear, and contain the various receipts, payments, and other transactions on their account during the proceeding six or

Bookcelling. It is a rule in the best managed counting-houses to despatch the accounts-current to the different correspondents as soon as possible after the day to which they are made up. To effect that, they ought to be copied out, in part at least, before the 31st December or 30th June, the dates at which they generally close, particularly as the interest and commission cannot be calculated until they are written out; and the whole has then to be copied into the account-current book.

Mode of computing Interest.—To do this correctly on the different sums in an account-current, it is requisite to take the number of days between each transaction, and the state at which the account-current is closed. Take, for example, a sum of L.531 paid on 5th October, and bearing interest consequently during eighty-seven days, until 31st December. On ascertaining the number of days, compute the interest, either by referring to a book of interest tables, or by the following operation.

Multiply the pounds, 531, by 87, the number of days, and the product will be 46,197; divide that sum by 7300, and the quotient, L.6, 6s. 7d., will be the interest required. The reasons for this process are as follows: interest at 5 per cent for one year forms a twentieth part of the principal, there being a shilling of interest for every pound of principal. On multiplying the number of pounds by the number of days, the product, 46,197, is so many 365th parts of a shilling; divide it by 365, and the quotient, L.126, 0s. 7d., will be the interest. But as it is desirable to have the quotient in pounds, alter your divisor so as to obtain it in that form; that is, multiply 365 by 20, and make the product 7300 your divisor, or, preferably, 73 by striking off two figures from it, and the same from the dividend: the quotient is the interest in pounds, shillings, and pence.

As to the comparative ease of the two processes, where the entries are few the interest tables may be used with advantage; but whenever they are numerous, as they very often are in accounts-current, it will save time to multiply and divide as above.

The product by that process gives the rate of interest at

And the remainder is the interest at 4 per

When accounts-current are made out, as in general they ought to be, every six months, the 30th June is the concluding date for the earlier half year. West-India houses are accustomed to balance their books and close their ac-

counts-current once a year, viz. on 30th April.

There are two modes of preparing accounts-current in a counting-house. The more usual course is to write them out from the ledger and journal, and afterwards to copy them into the account-current book. The other plan is to make no reference, in the first instance, to the ledger or journal, but to post the account-current book from the cashbook, bill-books, account-sales, invoices, and other authorities in the counting-house, so as to render it (the account-current book) a check on the ledger. This, however, is of less importance than may at first be thought, because, from the plan of the journal and ledger, omissions are not so likely to occur in them as in the account-current book; and the chief advantage of a separately posted account-current book consists in having it brought up to a day, as it may easily be at a time that the journal and ledger are in arrear.

Books of Account required by a Merchant.—Journal; ledger; cash-book; bills payable, or book of his acceptances; bills receivable, or book of bills on other merchants, to be paid to his order; order-book; bought-book, or book for bills of parcels delivered in; letter-book; invoice-book; account of sales book; insurance policy book; petty journal, or book for such occasional entries as are not inserted in the other books; petty cash-book, or book of petty disburse.

(J. L—E.)

BOOKSELLING. Among the Greeks the trade of the bookseller (βιβλιοκάπηλος) was unknown. It arose towards the end of the republican age at Rome, when the literary taste of the nobles demanded an increased supply of books. The Roman booksellers were called bibliopolæ, and sometimes librarii, though this term properly belonged to the slaves who were employed in the transcription of MSS., &c. The bookseller's shop was called libraria or taberna libraria. In Rome, the principal marts for books were the Argiletum, and the Vicus Sandalarius, as St Paul's Churchyard, Fleet Street, and Paternoster Row, have been in London. The great booksellers of the time of Augustus were the Sosii. (Cic. De Leg. iii. 20, Phil. ii. 9; Mart. iv. 71, xiii. 3, i. 4; Aul. Gell. xviii. 4; Hor. Ep. i. 20, 2; Ars. Poet. 345, &c.)

Booksellers are in many places ranked among the members of universities, and entitled to the privileges of students; as at Tübingen, Salzburg, and Paris, where they have always been distinguished from the vulgar and mechanical traders, and exempted from various taxes and impositions laid on other companies. An acquaintance with booksellers' marks or signs, as expressed on the title-pages of their books, is of some use, because many books, especially in the last century, have no other designation. The anchor is the mark of Raphelengius at Leyden; and the anchor, with a dolphin twisted round it, is that of the Manutii at Venice and Rome. The Arion denotes a book printed by Oporinus at Basle; the Caduceus or Pegasus, one printed by the Wecheliuses at Paris and Frankfort; the cranes, by Cramoisy; the compass, by Plantin at Antwerp; the fountain, by Vascosan at Paris, the sphere in a bal-

ance, by Janson or Blaew at Amsterdam; the lily, by the juntas at Venice, Florence, Lyons, and Rome; the mulberry tree, by Morel at Paris; the olive tree, by the Stephens at Paris and Geneva, and the Elzevirs at Amsterdam and Leyden; the bird between two serpents, by the Frobeniuses at Basle; the Truth, by the Commelins at Heidelberg and Paris; the Saturn, by Colinæus; the printing-press, by Badius Ascenius; and so of the rest. See BIBLIOGRAPHY.

The traffic in books was in ancient times very inconsiderable, so that the book merchants of England, France, Spain, and other countries, were distinguished by the appellation of stationers, as having no shops, but only stalls or "stands" in the streets. During this state the civil magistrates took little notice of the booksellers, leaving the control of them to the universities, of which they were supposed to be the more immediate retainers, and which accordingly gave them laws and regulations, examined the correctness and fixed the prices of their books, and punished them at discretion. But when, by the invention of printing, books and booksellers began to multiply, it became a matter of more consequence to regulate their proceedings; and hence sovereigns took the direction of the bibliopoles into their own hands.

As despotism and a free press are incompatible, wherever the power of the sovereign has been unlimited, or ecclesiastical authority has prevailed, the trade of bookselling has been put under rigorous restraints. It is only under free and constitutional governments that it is open and unrestricted.

In Britain the business of bookselling is carried on by three classes of tradesmen: 1st, Those who are chiefly en-

selling.

Bookselling. gaged in the publication of books, who may be considered as the manufacturers. 2d, The wholesale booksellers or middle-men, who purchase large numbers from the publishers, with the view of supplying from their extensive stocks the demands of the retail dealers. 3d, The retail booksellers, through whom the public are more directly supplied. The terms on which books are published vary according to the agreement made by the author with the publisher. Sometimes the bookseller purchases the copyright for a fixed sum, and takes the whole responsibility upon himself; sometimes the author and bookseller agree to divide the risk and the profit, or only the profit that may be realized on an edition or editions; or the author may publish on his own account, taking the chance of profit or loss upon himself, paying a commission to the bookseller on the amount of sales.

paying a commission to the bookseller on the amount of sales.

London is the great seat of the publishing trade in Great
Britain; the only other towns where it is prosecuted to any
considerable extent are Oxford, Cambridge, Edinburgh,
Glasgow, and Dublin. The following is the number of persons returned as booksellers and publishers in England and
Scotland at the census of 1851:—

England and Wales Scotland		Females. 858	Persons. 6905 1486
Total	7481	910	8391

In Ireland, from the calculation of an extensive bookseller in Dublin, the numbers are as follow:— Booksellers and publishers in Dublin 40 Shops for small periodicals in do. 20

In the other towns of Ireland 108

The editor of the *Publishers' Circular* says, that after careful calculation he finds that "the issues of new publications and new editions are now averaging together 4380 volumes per annum, which, after making full allowance for the improvements in our system of registration, shows an annual issue of nearly one-fourth over that of ten years back. This conclusion is drawn from a pretty safe average, that of four years, thus:—

1839 2 1840 2 1841 2 1842 2	091 ,, 011 ,, 193 ,,	New editions. 773 vols. 821 ,, 741 ,, 684 ,,
1839-42, 8	97,	3019—Total, 11,616 vols.
1849 3:	281	1062 vols.
1850 3	025 "	1186 ,,
1851 3	454 ,,	1016 ,,
1852 33	359 "	1140 ,,
1849-52, 13.1	19	4404—Total, 17,523 vols.

"This does not include pamphlets, of which we have only taken the record during the last three years:—In 1850, there were 1198; in 1851, 940; and in 1852, 908; the noticeable excess for the first year arising from the pamphletwriting on the Papal question, upon which there were no less than 180 published during one month."

The book trade of France is carried on much in the same way as in England.

From the last number of the Journal de l'Imprimerie for 1851 we gather the following statistics of the productions of the French printing-houses during the last ten years:

1842 6.445	18487.234
1843 6,009	
18446,477	
1845 6,521	
1846 5,816	
1847 <i>5</i> ,530	In ten years, 64,568

or an average per year of 6436 works. The same presses printed, in 1851, 485 musical works, and in the ten years 3336, or an annual average of 333.

There have also been published 1014 engravings and lithographs, and during the ten years 13,085, or an average of 1308.

Two hundred and fifty-three maps and topographical plans have also been published during the year; during the ten years 1005, or a mean of 100 a year.

Thus it appears that nearly in every department of presswork the year 1851 is in advance of the average of the last ten years. The grand total of works published in France during these ten years, engravings, musical works, maps, and plans, is 81,994.

The bookselling and publishing trade in Germany is differently organized from that of either England or France, and, upon the whole, is carried on by a class of persons of superior intelligence. The principal booksellers of Russia, Holland, Italy, and Hungary, are Germans or their descendants. In Germany there is a much larger number of publishers than in any other country of the same size, and they are not, as in Great Britain or France, confined to a few of the principal towns. but are scattered about over the whole country, though, of course, their chief sales are in the numerous small capitals and university towns. The German publishers generally, owing to the small cost of paper and print compared with the expense in England or France, and the comparatively small remuneration to the author, realize, if they sell the whole of an edition, a much larger per-centage of profits; but owing to the system there prevailing of sending almost all their works in the first year on sale to the different parts of the country, they are generally obliged, in order to give a book a fair chance, to print a much larger edition than there is any immediate prospect of selling. On the other hand, by this means of making known new books, very little is expended in advertising.

There are no wholesale booksellers in Germany, as the term is understood in England and France, the publishers being generally in direct communication with all the principal retail booksellers in every town on the Continent, many of them keeping as many as 1000 to 1500 trade accounts open. But every retail bookseller has his agent or "commissioner" at Leipzig, and sometimes in other towns in the south of Germany, to whom all parcels for him are sent and forwarded in one package once or twice a-week. This agent also acts as his banker with the trade, almost all payments being made at Leipzig from one agent to another, their weekly or bi-weekly settlements being carried on in a small way on the plan of the clearing-house of the Lon-At Easter, however, when the general don bankers. balances of all the booksellers connected with the German trade are made and paid on the booksellers' exchange at Leipzig, the sums are very considerable.

Owing to the facility with which the trade of publishing can be carried on in Germany, the absence of all difficulty in immediate communication with the whole retail trade creates a much larger number of publishers in proportion to the number of books published than elsewhere; in fact, almost every bookseller is a publisher to some extent. Nevertheless, the principal publications are in the hands of a limited number of publishers in the strict sense of the word; and, to some extent, they confine themselves to particular classes of publications.

In the United States of America the business of bookselling is carried on to a large extent, principally in books reprinted from English copyright works. These being produced at the mere cost of paper and printing, the authors deriving no benefit from their writings, the American

¹ In this case authors should keep in mind that they are, as far as the publication in question is concerned, copartners with the book seller, and in case of the bankruptcy of the bookseller they are liable for all debts against the book.

booksellers are enabled to sell at prices greatly below those of the English market. Of late years, however, they have published many valuable original works, chiefly in theology,

law, and natural history.

The publisher of Norton's Literary Gazette estimates the number of volumes published in the United States from July 1850 to July 1851 at 1298, embracing 213,049 pages, and forming 1176 distinct works. The principal towns in which the bookselling business is carried on in the United States are Boston, in which there are 78 booksellers and publishers; New York, in which there are about 130; and Philadelphia, in which there are about 120. In Baltimore, Cincinnati, St Louis, as well as in all the considerable towns throughout the United States, some books are published; and everywhere there are retailers of school and miscellaneous books.

Repeated attempts have been made to induce the American legislature to sanction an international copyright law. Committees of the senate have reported in favour of the measure, but the lower house, composed of the representatives of the people, have constantly resisted it; nor is it likely they will agree to a measure, though just in itself, which would prevent their constituents from appropriating the productions of British authors at a greatly reduced price, and which might at the same time diminish the trade of paper-makers, printers, bookbinders, and all engaged in the manufacture of books. (See COPYRIGHT.) From the low price at which the reprints of popular English books can be produced, the sale is often four or five times greater than in Britain. It is calculated that 125,000 copies of Macaulay's "England" were sold in America, when scarcely a fifth of that number were sold in Britain. The profit of these, at the selling price of 32s. or \$8, would amount to \$1,000,000, but as they were supplied at 80 cents, the profits amounted to only 100,000. In this case there is no remuneration to the author, the type is small, and the paper thin and inferior; and as a large sale can be calculated on with certainty, very large editions are thrown off by machinery, so that the cost is reduced to little more than that of the paper. "But it will be asked," says Mr Carey,1 "is it right that we should read the works of Macaulay, Dickens, and others, without compensation to the authors? In answer it may be said that we give them precisely what their own countrymen have given to their Dalton, Davy, Parry, and the thousands of others who have furnished the bodies of which books are composed, and more than we ourselves give to the men among us engaged in cultivating science—fame." Authors have often had but scanty fare, but if they were confined to Mr Carey's luxuries their condition would hardly be improved. Mr Carey informs us that there have been sold in the United States in five years 80,000 volumes of the 8vo edition of the Modern British Essayists; of Macaulay's . Miscellanies, in 3 vols. 12mo, 60,000 volumes; of Miss Aguilar's writings, 100,000 volumes in two years; of Murray's Encyclopadia of Geography, more than 50,000; M'Culloch's Commercial Dictionary, 10,000; of Alexander Smith's poems, in a few months, 10,000. The sale of Thackeray's works has been quadruple that of England, and that of Dickens' works counts by millions of volumes. Bleak House alone sold to the amount of 250,000 in volumes, magazines, and newspapers. Bulwer's last work reached about two-thirds of that number; Alison's Europe 25,000 copies; of Jane Eyre there have been sold 80,000.

The universality of education in the United States is the main cause of an extensive publication of books. Everybody must learn to read and write, and everybody must have books; hence the great circulation, not only of foreign but of domestic literature. The sale of many of their more popular works, especially of educational publications, is prodigious:

the sale of the works of Peter Parley counts by millions; of Book-Morse's Geography and Atlas (50 cents), not less than 70,000 are sold yearly; of Abbots' histories, 400,000; Emerson's Arithmetic and Reader count almost by millions; of the Boston Academy's collection of sacred music, costing a dollar per volume, the sale has exceeded 600,000: and the aggregate sale of five books by the same author has probably exceeded a million. Of Webster's Dictionary in 4to (price \$6), the sale has reached from 60,000 to 80,000 volumes, and of the royal 8vo (\$3.50), 250,000. Of all American authors, excepting the writers of school-books. Washington Irving has circulated the greatest number of volumes. Prior to the publication of the edition of his works by Mr Putnam, the sale had amounted to some hundreds of thousands, and yet of that edition, selling at 5s. per volume, the sale has already risen to 144,000 volumes. Of Uncle Tom's Cubin the sale has amounted to 295,000 copies. Of the works of Prescott, Bancroft, Kent, Barnes, Hawthorn, Longfellow, Bryant, Willis, Curtis, Sedgwick, Sigourney, and many others, the sale is exceedingly great. The copyright of Judge Story's books is understood to yield above L.1600 a-year, and other American authors have received large sums for their copyrights. The term of the copyright is the same in the United States as in Britain-forty-two years.

The number of semi-monthly, monthly, and quarterly journals, according to the last census, was 175. Every pursuit in life, and almost every shade of opinion, has its periodical. Dental surgery alone has five, while in all Europe there are but two. The proportion which republications of British books bore to original works published in America during the six months ending June 30. 1853, was 169 republica-

tions to 522 original.

"Less than half a century since," says Mr Carey, "the race of literary men was scarcely known in the country, and the amount now paid for literary labour is greater than in Britain and France combined, and will probably be in twenty years greater than in all the world beside." This is certainly an American exaggeration: liberal as the remuneration has been to authors in the United States, it is not to be compared to the sums paid for copyrights in Britain; but looking forward to the next century,—when the English language shall be spoken in the whole of North, and in a great part of South America, when new nations of the Anglo-Saxon race will occupy Australia, and when the English colonies in all quarters of the globe shall have extended their boundaries and increased their inhabitants, and when education shall have been universally spread,—what a glorious prospect opens for the English authors and booksellers of future generations!

The profits allowed to booksellers appear to the superficial observer unreasonably large; but that they are probably smaller than those of other trades is proved by the fact that the same amount of capital, industry, and intelligence employed in other branches of business, is generally found to yield a larger income to those engaged in them.

The selling price of a book, compared with the cost of the paper, printing, and binding, appears extravagant; but let us follow the process by which the individual volume reaches the individual reader. The reader in Edinburgh desires his bookseller to supply him with a volume published in London at 20s.; he writes to his usual correspondent, as it is impossible to keep accounts with every publisher; if his correspondent allows 25 per cent. he will expect 10 or 15 from the publisher for himself; and before the volumes reach their ultimate destination, many of them percolate through three or four different hands, each entitled to a share of profit which is not too much for risk, &c.; so that before the demand reaches the original publisher, in many instances, he does not receive a half of the selling price,

Boom Boorhanpoor.

and is glad at the end of three or four years, if, besides the loss of interest of money, he has not a large proportion of

the edition lying on his hands as waste paper.

In 1852 the booksellers of London formed a kind of trade-union, by which they attempted to exclude from the trade all who would not keep up their prices to what was called the regular rate. This, like all associations of the kind, soon fell to pieces, and various plans were proposed by which the readers might be furnished with books at a smaller deduction from the cost of production. It has not, however, been found possible to dispense with the machinery by which the productions of the press can be distributed through the mass of readers; and this convenient machinery must be paid for till one less costly be discovered which will accomplish its objects as well. (A. B.)

BOOM (Dutch, boom, a beam), in naval language, a long spar for spreading out the clew or corner of particular sails; as the jib-boom, studding-sail boom, main-boom, squaresail boom, &c.

Boom denotes also a strong chain or cable stretched across the mouth of a river or harbour, with spars lashed to it, to prevent the entrance of an enemy's ships.

BOOMERANG, a missile instrument of the Australian aborigines, with which they are said to be very dexterous in hitting birds. It consists of a piece of hard wood, with the curve of a parabola, and is about 2 feet long, $2\frac{1}{2}$ inches broad, \frac{1}{3} inch thick, and rounded at the extremities. One side is flat, the other is rounded, and it is brought to a bluntish edge. It is discharged with the hand by one end, the convex edge being forward and the flat side upwards. After advancing some distance, and ascending slowly in the air with a quick rotatory motion, it begins to retrograde, and finally falls to the ground behind the projecter. The principle of the boomerang has been attempted to be applied to the propulsion of ships. See STEAM NAVIGATION.

BOOMING, among sailors, denotes the application of a boom to the sails, in order to accelerate the speed of the

BOONDEE, a town of Hindustan, in the province of Rajpootana, situated on the southern declivity of a long range of hills which run nearly from east to west. The palace of the rajah is a massive building of stone, and was intended to serve as a fortress, though it would not be long tenable against modern tactics and artillery. The territory of which this town is the principal place contains an area of 2291 square miles, and a population estimated at 230,000; and the revenues of the rajah are returned at L.50,000 per annum. During the progress of the Pindarrie and Mahratta war, this prince had espoused the cause of the British, and shown himself a warm supporter of their views; and upon its termination in 1818, a treaty of alliance was concluded between the two governments, containing the usual stipulations of friendship and protection on the part of the paramount power, and of subordinate co-operation on the part of the allied state. Boondee is distant from Delhi, southwest, 245 miles. Lat. 25. 26. Long. 75. 43.

BOORHANPOOR, a decayed town of Hindustan, in the territory of Gwalior, or possessions of the Mahratta family of Scindia, situated on the north bank of the river Taptee. It was formerly a large and flourishing city, being the seat of government of the kings of Candeish, one of whom, Malik Nasir, founded it in the year 1414. Akbar, emperor of Delhi, annexed it with the adjacent territory to the imperial dominions in 1599; and during the reign of his son Jehangir it was visited by the English ambassador Sir Thomas Roe, on his route from Surat to the Mogul court. In the early part of the last century it was mrested from the empire by the Nizam of Hyderabad, and at a later period became the prize of Madhajee Scindia in his rapid career of conquest. During the Mahratta war of 1803 it was occupied by Colonel Stevenson's army without opposi-

tion, but restored at the conclusion of the peace in December following. Distance from Oojein 132 miles; from Bombay 280. Lat. 21. 18. Long. 76. 20.

BOORO, an island in the Asiatic Archipelago, situated between Lat. 3. and 4. S. and Long. 126. and 127. E. It is of an oval shape, and may be estimated at seventyfive miles in length by thirty-eight in average breadth. This island is fruitful, producing large quantities of rice, sago, oranges, Iemons, citrons, cocoa-nuts, bananas, and pine-apples; also the cajeput tree, from the leaves of which the cajeput oil is procured. Fine timber grows on this island, and many kinds of beautiful wood, fit for inlaying; besides black and wnite ebony, and the palm and the teak trees. Ships may be supplied here with rice, cattle, and other refreshments; and the woods abound with wild boars, goats, and deer, and, among the latter, the babyrussa, or true hog-deer, as its name implies. The natives consist of two races, the aborigines, who live in the interior of the island among inaccessible mountains, and of whom little is known; and the Moors or Mahometans, who inhabit the northern coast, and acknowledge the authority of the Dutch.

BOOROOJIRD, a flourishing city of Persia, in the province of Irak, situated at the foot of a mountain. It is the chief town of a district peopled by a tribe called Lack, who seldom wander far from the spots to which they are partial, but settle in villages, and employ themselves in the improve-ment of their estates. Population, 12,000.

The Chinese trade here for cabinet woods and different species of dye-woods. At Cajelli bay on its north side there is

good anchorage, and at the east end is a Dutch station.

BOOT, a defence of leather for the foot and leg. Boots seem to have derived their name from their resemblance to a sort of jacks or leathern bottles formerly in use, called bottæ in Latin, and in the old French bouts.

Boot, an instrument of torture, by which the leg was squeezed with great violence, for the purpose of extorting confession. (See Wodrow's Hist. of the Sufferings of the Church of Scotland.)

BOOTAN. This extensive region is situated between Bound-Bengal and Tibet, and between the 26th and 29th degrees aries. of north latitude. To the north it is separated from Tibet by the eastern ridges of the Himalaya range; Assam and Goalpara, with the native state of Cooch Behar, form its boundaries to the south; on the east it is bordered by a tract inhabited by uncivilized mountain tribes; and on the west by the native state of Sikkim. Its length from east to west is 230 miles, its breadth 120, and the area contained within its limits falls little short of 20,000 square miles. A slip of land varying from ten to twenty miles in breadth extends along the base of the mountains from east to west, and separates the hill-country of Bootan from the province of Bengal. With the exception of this narrow tract, the Physical whole of Bootan presents a succession of lofty and rugged Aspect. mountains, abounding in the most picturesque and sublime scenery. "The prospects," says Captain Turner, "between abrupt and lofty prominences were inconceivably grand; hills clothed to their very summits with trees, dark and deep glens, and the high tops of mountains lost in the clouds, constituted altogether a scene of extraordinary magnificence and sublimity.

As might be expected from the physical structure and elevation of this alpine region, numerous rivers are sent forth in a southerly direction, which, forcing their passage through narrow defiles, and precipitated in tremendous cataracts over frightful precipices, eventually pour their tributary streams into the Brahmapootra. One torrent is mentioned by Turner as issuing from the high grounds in a collected body, but as descending from so great a height that before it reaches the thick shade below it is nearly dissipated, and appears like the steam arising from boiling water. Of the rivers traversing Bootan, the most considerable is the Monas,

Boore Bootan.

which in its progress to the Brahmapootra flows under the walls of Tassgong, beyond which place it is unfordable. At the foot of Tassgong Hill it is crossed by a suspension bridge. The other principal rivers are the Matchoo, the Tchinchoo, the Toorsha, the Manchee, and the Durla.

The more southern portions of the plains of Bootan bordering upon Bengal are under rice cultivation. Between the cultivated tracts and the mountains occurs an intervening space covered with the most luxuriant vegetation, but pervaded by an atmosphere so deleterious to the human constitution that even those most inured to the climate rarely pass through it with impunity. In the hilly part of the country the climate varies according to the difference of elevation. At the time when the inhabitants of Punakha (the winter residence of the rajah) are afraid of exposing themselves to an almost vertical sun, those of Ghassa experience all the rigour of winter, and are chilled by perpetual snows; yet both these places are within sight of each other. On the elevated mountain heights it is cold and moist, and here the clouds are intercepted and descend in rains. The rains, however, in the vicinity of Tassisudon, the capital, are moderate. There are frequent showers, but nothing that can be compared to the tropical rains of Bengal. Owing to the great elevation and steepness of the mountains, dreadful tempests of winds arise among the hollows, which are often attended with fatal effects. A considerable village, situated on the brow of a lofty hill, was nearly destroyed by one of these tempests. In one night a hurricane swept nine houses with their unfortunate inmates down the steep; and though search was afterwards made, not the slightest trace of them was ever found. Three houses remained; and their tenants, unawed by the dismal fate of their neighbours, still retained their occupation.

The people are industrious, and devote themselves to agriculture, but from the geological structure and physical aspect of the country, the pursuits of husbandry, except in the plains, which are under rice cultivation, are limited to comparatively few spots. In the vicinity of the cottages which are interspersed throughout the mountains, the land is cleared for cultivation, and produces thriving crops of barley, wheat, buckwheat, and others of less importance. Turnips of excellent quality are extensively grown; they are free from fibres, and remarkably sweet. The climate is generally well adapted to the production both of European and Asiatic fruits and vegetables. Potatoes have been introduced, but the cultivation of this valuable root has not been attended with success. The forests abound in a variety of stately trees. Among them are the beech, ash, birch, maple, cypress, and yew; firs and pines cover the mountain heights; and below these, but still at an elevation of eight or nine thousand feet, is a zone of vegetation, consisting principally of oaks and rhododendrons. these mountains, in the vicinity of Murichom, grows the cinnamon tree. Some of the roots and branches were examined by Turner in the course of his journey to Tibet; but the plant being neither in blossom nor bearing fruit, it was impossible to decide whether it was the true cinnamon or an inferior kind of cassia. The leaf, however, corresponded with the description given of the true cinnamon by Linnaus.

Notwithstanding the great diversity of climate, the uninclosed character of the country, and the difficult fastnesses in which it abounds, there is no great variety nor large number of wild animals. Thickets of dense vegetation extend along the base of the mountains, and afford shelter to the elephant. tiger, buffalo, and deer. But in the hills of Bootan wild animals are extremely rare; and Turner mentions, as an extraordinary circumstance, that he one day saw a multitude of monkeys playing their gambols by the road side. They are of a large and handsome kind, with black faces surrounded by a streak of white hair, and have very long slender limbs. They are held sacred by the Booteans as well as by the Hindus. The horse, a certain species of which is indigenous to Bootan, and is used as a domestic animal, is called tangun, from Tangustan, the general appellation of that assemblage of mountains which constitutes the territory of Bootan. It is peculiar to this tract, not being found in any of the neighbour-

ing countries of Assam, Nepaul, Tibet, or Bengal, and unites Bootan. in an eminent degree the two qualities of strength and beauty, being remarkable for symmetry and just proportions. The Tangun horse is usually about thirteen hands high, shortbodied, clean-limbed, and deep in the chest, yet extremely active. Being constantly accustomed to struggle against acclivities, there is a surprising energy and vigour in all his movements; and this indomitable spirit is supposed by Europeans to proceed from a headstrong and ungovernable temper, while in reality it is only an excess of eagerness in the performance of any allotted task. The colour of this horse usually inclines to piebald, and those of one colour are rarely to be found.

The Booteans are not a warlike people, and the military re- Military sources of the country are altogether on an insignificant scale. resources. Beyond the guards necessary for the defence of the various castles, there is nothing like a standing military force in the country. An insuperable difficulty to the maintenance of such a force would, indeed, be presented in the inadequacy of supplies, and the great distance from which they must be drawn.

In so barren and rude a country the manufacturing industry Manufacof its people must necessarily be at a low ebb, and the few tures. articles produced are all destined for home consumption. These consist of coarse blankets and cotton cloths, made by the villagers inhabiting the southern tract bordering upon British territory. Leather, from the hide of the buffalo, imperfectly tanned, is principally used for the soles of snow-boots. Circular bowls are neatly turned from various woods. A small quantity of paper is made from the plant described as the Daphne papyrifera; and, if to these be added the straight sword worn by the men, iron spear and arrowheads, and a few copper caldrons fabricated from the metal obtained in the country, the list of the manufactures of Bootan may be considered nearly complete.

The inhabitants of this elevated tract are of active habits Inhabitand of a herculean make, many of them being six feet high, ants. and are entirely different from the feeble and timid natives of Bengal. A general resemblance of features pervades the whole race of these hardy mountaineers. They are fairer than their Bengal neighbours, and have generally broader faces, with high cheek-bones. They have invariably black hair, which it is their fashion to cut close to the head. The eye, which is a remarkable feature in their face, is small and black, with long pointed corners, as if stretched and extended by artificial Their eye-lashes are so thin as to be scarcely percep-Their face is rather flat, narrowing from the checkbones to the chin, and broadest below the eyes,—a physiognomy which somewhat resembles that of the Tartars, though it is far more strongly marked among the Chinese. They have very small beards, and generally reach an advanced age before they have the appearance of any; in this also resembling the Tartars. They are social and cheerful in their manners. The women and the men mix freely together; and they are frequently seen sitting under the cavities of the rocks or other sheltered places, chatting together in great good humour, and occasionally indulging in obstreperous laughter. They generally exhibit a picture of rosy health; the women in particular, with their jet black hair, and clear, brisk, black eyes, possess a ruddiness which, according to Turner, the most florid English rustic would in vain attempt to rival. Yet they are far from being cleanly in their habits; nor are their manners and amusements of a refined cast. Their mode of living is simple; their food consisting of fruits, vegetables, and roots. Tea is as common a refreshment as in China, but the mode of preparation is by an admixture of water, flour, butter, and salt. A spirit is extracted from rice, wheat, barley, and other

The supreme ruler of Bootan is called the Deb Raja. Govern-He resides at Tassisudon, and possesses unlimited sway ment; over his subjects. The people follow the religion of Religion; Buddha; and the priests form a distinct class, and are bound by the most rigid vows of celibacy. They are dispersed throughout the country in monasteries, and other buildings appropriated to their use. The Deb Raja has always manifested the strongest inclination to extend his territories by incroaching on those of his neighbours. In 1772 he suddenly invaded the principality of Cooch Behar, a dependency of Bengal; but its rajah having applied to

Bootes
Booton.

the British for aid, a force under Captain Jones was despatched to Cooch Behar, by means of which the invaders were expelled and pursued into their own territories. Upon meeting with these reverses, the Booteans implored the assistance of the Tibetan authorities: in compliance with the request of the Teshoo Lama, then regent of Tibet, a cessation of hostilities ensued, and in 1774 a treaty of peace was concluded between the East India Company and the ruler of Bootan. In 1783 Captain Turner was deputed to Bootan, with a view of promoting commercial intercourse, but his mission was not regarded as successful. From this period little intercourse took place with Bootan, until the occupation of Assam by the British in 1826. It was then discovered that the Booteans had usurped several tracts of low land lying at the foot of the mountains, called. dooars or passes, and for these they then agreed to pay a small tribute; but failing in their obligations, and availing themselves of the command of the passes to commit depredations in the British territories, Captain Pemberton arrived in Bootan in 1837, commissioned to adjust the points of difference. His negotiation was productive of no definite result; and every other means of obtaining redress and security proving unsuccessful, the dooars were wrested from the Booteans, and placed under British management. (E. T.)

BOOTES, a constellation of the northern hemisphere. It contains Arcturus, a star of the first magnitude.

BOOTH, BARTON, a celebrated English tragedian, born of an ancient family in Lancashire, in 1681. He was educated in Westminster school under the celebrated Dr Bushby, where his success in the Latin plays customarily performed by the scholars gave him an inclination for the stage. He was intended for the church; but at seventcen years of age he ran away from school, and joined a theatrical company at Dublin. His first appearance was hailed with applause; and from this time he continued daily improving. After two successful campaigns in Ireland he returned to his native country, having first reconciled himself to his friends. Betterton, to whom he had an introduction, received him with great cordiality, and gave him all the assistance in his power. His success at London was complete, and he established his reputation as only second to his great instructor. He was indebted to a happy coincidence of merit and chance for that height of fame which he at length attained in the character of Cato. The Whigs, in favour of whose principles this tragedy was apparently written, thought it their duty to support it strongly; while the Tories, at every passage susceptible of a popular turn, were no less vehement in their approbation. Booth was twice married; first to a daughter of Sir William Barkham, Bart., and afterwards to Miss Hester Santlow, an actress of great merit. During the twenty years of his management, the theatre was in the greatest credit; and his death, which happened on the 10th of May 1733, contributed not a little to its decline. Booth was a man of excellent character, and greatly esteemed for his amiability and goodness of heart.

BOOTHIA FELIX, an extensive peninsula of British North America, between Lat. 69. and 75. N. and Long. 92. and 97. W. It was discovered by Captain, now Sir J. Ross, in 1830, and named after Sir Felix Booth. It forms the western side of the gulf of the same name, into which Prince Regent's Inlet leads from Baffin's Bay. It is almost separated from the American shores by a chain of lakes; and is perhaps joined to North Somerset, discovered by Sir E. Parry in 1819.

BOOTON, an island in the Eastern Archipelago, situated off the south-eastern extremity of Celebes, about the 5th degree of south latitude. It is estimated at eighty-five miles in length by twenty miles in average breadth. It is separated from the island of Angaosani by a narrow strait; and is productive, yielding rice, maize, yams, and a variety

of tropical fruits. The inhabitants are of a short stature and tawny complexion. They speak the Malay language, and are Mahometans. The Dutch had formerly a settlement here in the bay of Booton; and used systematically to destroy the clove-trees of the island.

BOPAL, an extensive town of Hindustan, in the province of Malwah, surrounded with a stone wall, on the outside of which is a large gunge or mart, with wide and straight streets. On a rising ground to the S.W. of the town is a fort called Futtehgur, built on a solid rock, and surrounded with square towers. Under the walls of the fort is a tank or lake four miles and a half in length.

The territory of which this town is the principal place contains an area of 6764 square miles, and belongs to a native chief, whose revenues amount to L.220,000 per annum. The political relations of the British government with this state commenced in 1818, when a treaty was concluded, the leading articles of which are of the usual character—protection by the British government, and acknowledgment of its supremacy by that of Bopal, with a stipulation for subordinate co-operation.

The state of Bopal boasts of no great antiquity. Its founder, Dost Mahomed Khan, exercised subordinate authority within its limits, under the Emperor Aurungzebe, at the commencement of the eighteenth century; and, upon the death of that prince he assumed the title of Nawaub. Subsequently Bopal attracted some notice; first, in 1778, from the circumstance of its ruler rendering assistance to a British force under General Goddard, which traversed a large part of India through states then, with the exception of Bopal, all unfriendly; and again, in 1813, when the city of Bopal sustained a nine months' siege from a combined Mahratta force amounting to at least six times the number of the garrison, by whom the assailants were ultimately compelled to abandon their attempt. The Nawaub, with whom the British treaty of 1818 was concluded, died shortly afterwards from the effect of an accidental pistol shot, and was succeeded by an infant nephew, between whom and the daughter of the deceased prince, also of tender age, a marriage was negotiated. When, however, the age of the young prince entitled him to look for admission to actual power, his claim was opposed by the Begum, widow of the deceased Nawaub, a woman of some ability, and who had enjoyed since the death of her husband a large share of influence and authority. She disputed not only his right to the throne, but also the claim founded on his betrothal to the infant heiress, and he was obliged to relinquish both in favour of a younger brother, who, however, when the time came for asserting his rights, received similar treatment from the Begum, who was resolved to retain her position at the head of the state as long as possible The prince's marriage at length took place, but sovereignty was still withheld, and would have been withheld so long as the Begum lived, had not arms achieved what negotiation was unable to accomplish. The new ruler did not long survive his recognition, and as his daughter, a child only six years old, was his successor, the necessity of the case enforced the re-establishment of a regency, in which the Begum managed finally to gratify her ambition and love of intrigue by attaining a chief part. Such is the present state of affairs in Bopal, where he who shall be so fortunate as to secure the person of the youthful princess in marriage will hereafter wield the sceptre of authority

BORACIC ACID (Sassoline or native boracic acid; boraxsaure), in Mineralogy, the only known compound of boron and oxygen, occurs in white pearly scales, which are soft and greasy to the touch, and have an acidulous taste. It fuses easily in the flame of a candle, and yields a glossy globule, which on cooling becomes opaque if any gypsum be in combination. When dissolved in alcohol it communicates to the flame a fine green tinge; a test which affords the

specific gravity is equal to 1.48; and, according to Berzelius, art of war. it consists of boron 25.83, and oxygen 74.17. The most celebrated deposit of this substance is the Solfatara, within the sublimated in the form of a thin filament or cake on the surface of the sulphur and around the fumaroles, whence it arises. These incrustations are usually about an inch in thickness, have sometimes a fibrous structure, and are always more or less tinged with sulphur. It occurs both massive and pulverulent; in which last case the particles form merely acid is likewise deposited by several of the lagunes in Tuscany, and at the hot springs of Sasso, a locality which has procured it the trivial name of Sassoline. The mineral from these deposits, however, differs materially in appearance from that of Volcano. It is grayer in colour, considerably harder, and shows traces of indistinct crystallization. Klaproth found that the Tuscan variety contains cleven per cent. sulphate of magnesia, an ingredient totally foreign to that from Volcano.

BORAK, a fabulous animal, on which Mahomet was supposed to have been carried in his nocturnal flight from Jeru-

salem to heaven.

BORASSUS, a genus of the natural order of Palmæ. The best known is B. flabelliformis or Toddy-palm, which in India yields a vinous juice and much sugar. This palm is 20 feet high, the leaves 4 feet long on foot-stalks of the same length. The juice is obtained by crushing the inflorescence, cutting off the upper part, and fastening the lower part to a vessel of bamboo, into which it drains. The fruit has the bigness of a small human head.

BORAX, in Mineralogy; borate of soda, tinkal, soude boratée. This salt is usually of a white or gray colour, translucent, feebly alkaline to the taste, soluble in water, and consists, according to Klaproth, of soda 14.5, boracic acid 37.0, and water 47.0. It intumesces before the blow-pipe, and then melts into a transparent globule: when in solution it changes the blue colour of litmus into green. Its chief locality is Tibet, where it is found on the surface of the soil, in the vicinity and at the bottom of certain lakes. It is there collected and sent to Europe in the form of a brownish-gray impure salt, from which the artificial borax is obtained by the addition of a greater quantity of soda. It is made use of as a flux, in forming imitation gems, and in the process of soldering. It is also of great utility in analysis by the blowpipe, and in some cases in glass manufactories. See CHE-MISTRY and MINERALOGY.

tical astronomer, celebrated for his improvements in the theory of hydraulics and pneumatics, and in the construction of instruments for observation. He was born at Drax, on the 4th of May 1733, and was originally destined for the bar; but abandoned the pursuit of the law in favour of a afford him opportunities for the cultivation of his mathematical talents, and for the application of the results of his studies to practice. His acquirements in science had very early attracted the attention of D'Alembert, who his turning his thoughts to the occupation of a place in the academy. He obtained a commission in the light cacorps; and, in 1756, he presented to the Academy of Sciences (A) A Memoir on the Paths of Bombs, which was ordered to be printed in the collection of the Savans Etranin the capacity of aid-de-camp to the celebrated General by methods before in use

Boracite best possible indication of the presence of boracic acid. Its Maillebois, to whom he looked up as a great master in the Borda.

He was afterwards admitted into the corps of engineers, without the usual form of examination into his qualificaancient crater of Volcano, one of the Lipari isles, where it is tions; and being stationed at a sea-port, the occurrences of the place naturally directed his attention anew to the phenomena of the resistance of fluids. He published, in 1763, a detailed memoir on this subject (B. Mém. Ac. Par. 1763, p. 358), in which he relates a variety of experiments, showing that the resistance of the air is actually proportional to the square of the velocity, as had coma filament or loose covering on the surface of the sulphur, monly been supposed from theoretical considerations. He without any attachment or adhesion to each other. Boracic also determines, by other experiments, the magnitude of the resistance to the motion of a sphere, and proves that nothing can be more erroneous than the supposition that the resistance to an oblique surface decreases as the square of the sine of the angle of incidence. He also finds, that the resistance to the motion of a cube, in the directions of the diagonal of its base and of one of the sides, are as 21 to 16, while the calculations of former theorists had made the resistance greatest in the direction of the side.

In 1766 he published an Essay on the discharge of fluids through the orifices of vessels (C. Mém. Ac. Par. 1766, p. 579), in which he first states the objections to considering the different strata of a fluid as descending in all cases very nearly in parallel directions; he examines the contraction of the jet after its escape from the orifice, and determines some of the effects of abrupt changes in the velocity of the fluid passing through pipes or apertures

of different forms.

He contributed, in 1767, to the publications of the academy, an important Memoir on Water Wheels (D. p. 270), which has escaped the notice of his able biographer M. Lacroix. He observes, in this paper, that the simple hypothesis of a resistance varying as the square of the velocity, which is so near the truth in common cases, where a number of particles, proportional to the velocity, strikes, in a given time, upon a small exposed surface with a force also proportional to the velocity, is totally inapplicable to the action of a confined stream upon the floatboards of a wheel, since in this instance the number of particles concerned cannot vary materially with the velocity, the whole stream being supposed to operate in all cases upon the successive floatboards; so that the analogy would require us to suppose the force in this case nearly proportional to the simple relative velocity; a conclusion which agrees remarkably well with the experiments of some practical authors.

The same volume contains a continuation of M. Borda's BORDA, John Charles, a mathematician and nau-researches relating to the resistance of oblique surfaces (E. Mém. Ac. Par. 1767, p. 495), with a statement of experiments still more conclusively confuting the received hypothesis respecting oblique impulse than his former investigations had done. We also find in it an Essay on isoperimetrical problems (F. p. 551), in which it is shown military life, which he considered as better calculated to that Euler's method of treating them, which had been in great measure abandoned by its equally profound and candid author, in favour of the more general and more elegant calculations of Lagrange, was still capable of affording all the results that had been derived from the mepredicted his future eminence, and warmly recommended `thod of variations; and he even pointed out some deficiencies in the first memoir of Lagrange, which contained the detail of his ingenious invention. These investigations of valry, and was appointed teacher of mathematics to the M. Borda afford collateral evidence of the strict truth of the demonstrations of both his great predecessors; and though they have been little employed by later mathematicians, yet it must be admitted to be of some importance, gers, but which has not excited much attention. He was in enabling us to appreciate the value of a new mode of elected in the same year a member of the academy; and calculation, to determine whether its results are or are not in the next he was present at the battle of Hastinbeck, such as might be obtained with almost equal convenience

Borda.

His memoir, inserted in the collection of the Academy for 1768 (G. Mém. Ac. Par. 1768, p. 18), is devoted exclusively to the theory of pumps; and he considers especially the effect of the passage of the fluid through valves and other contracted parts in diminishing the quantity of the discharge. His results are derived from the principle of the preservation of the living force or energy of a system of bodies, throughout all the vicissitudes of its motions, which had before been employed with success by Daniel Bernoulli in problems of a similar nature; but it was not until the experiments of Buat had afforded sufficient grounds for the determination of the friction of fluids, that cases of this kind could be submitted to exact

In his Essay on the curve described by cannon-balls, published among the Memoirs for 1769 (H. Mém. Ac. Par. 1769, p. 247), he has greatly simplified the practical theory of projectiles, which had been treated in a satisfactory though very general manner by John Bernoulli, and had been reduced into a much more convenient form by Euler. M. Borda has substituted some approximate expressions for the true value of the density of the air, and has thus been enabled to integrate equations which, in their more strictly correct form, had resisted the powers of Euler himself; and he has justified the adoption of the formulas thus obtained by a comparison with experiment.

In the mean time his talents were very actively employed in the naval service of his country, which he entered in 1767, by the nomination of M. Praslin. time-keepers of Le Roy and Berthoud were beginning to rival those of the English artists, and the French government ordered several vessels to be fitted out for cruises, in order to examine the accuracy of these time-keepers. M. Borda was appointed a lieutenant on board of the Flore, and acted jointly with M. Pingré as a delegate of the Academy of Sciences for the purposes of the expedi-The voyage occupied about a year, and extended to the Canaries, the West Indies, Newfoundland, Iceland, and Denmark. M. Borda had a considerable share in the account which was published of the observations; and the formula which he has here given for the correction of the effects of refraction and parallax is considered as equally elegant and convenient. He also presented to the academy a separate memoir on the results of the expedition. (I. Voyage pour éprouver les Montres de Le Roy. 4. Paris. K. Mém. Ac. Par. 1773, p. 258.) After an interval of six weeks, these watches were found capable of determining the longitude within about fifteen minutes of the truth.

In order to supply some deficiencies in the observations made at the Canaries, Borda was sent out a second time, with the Boussole and the Espiègle; and he published, after his return (L.), a very correct and highly finished map of these islands. He was soon afterwards promoted to the rank of captain, and served under the Count d'Estaing as a major-general, an appointment nearly similar to that of our captains of the fleet. In this capacity he observed the inconvenience of too great a variety in the sizes of the vessels constituting a fleet, and proposed to abolish the class of fifty and of sixty-four gun ships, as too small for the line of battle, and to build ships of three rates only, the lowest carrying seventy-four guns, so that a smaller quantity of stores should require to be kept ready for use in the dock-yards, than when ships of more various dimensions were to be refitted. In 1780 he had the command of the Guerrier, and in 1781 of the Solitaire,

adopted by that body. Its peculiarity consisted in hav- Borda. ing the names of the candidates arranged by each voter in a certain order, and collecting the numbers expressing the degrees of preference into separate results, so that the simple majority of voters did not necessarily establish the claim of any individual, if he was placed very low in the list by any considerable number of those who voted against him. But it must be allowed that this mode of election is by no means wholly unobjectionable.

M. Borda appears to have rendered an essential service to the cultivators of practical astronomy by the introduction and improvement of the repeating circle, although this instrument has probably been less employed in Great Britain than elsewhere, on account of the greater perfec tion of those which were previously in common use. It had been suggested by Mayer in 1767, that a circle with two movable sights would enable us to observe a given angle a great number of times in succession, and to add together the results, without any error in reading them off, and thus to obtain a degree of precision equal to that of much larger and better instruments of a different construction; but the proposal had been little noticed until ten years afterwards, when Borda pursued the path pointed out by Mayer, and trained Lenoir, then a young and unlicensed artist, to the execution of the improved instrument, notwithstanding the opposition of the rival opticians, and the want of encouragement from the opulent public. He published in 1787 (N.) his Description and Use of the Reflecting Circle, with different Methods for Calculating the Principal Observations of Nautical Astronomy; but the officers of the French navy, for whom this work was intended, appear to have profited but little by his instructions. His instrument was, however, much employed in the operations for determining the length of the terrestrial meridian; and he himself took charge of the experiments required for ascertaining the length of the pendulum, and for the comparison of the different standards with each other. He invented some very ingenious methods of overcoming the difficulties which present themselves in the pursuit of these objects; but he was interrupted in his researches by the horrors of the Revolution, nor did he live to see the whole of the operations completed. He endeavoured, also, to promote the introduction of the new mode of subdividing the circle, by the laborious computation of Tables of Logarithms (O. 4to, Par. 1801) adapted to decimal parts of the quadrant; a work in which he was assisted by M. Delambre. From the increasing indisposition of M. Callet, who had undertaken to correct the proofs of these tables, some very material errors had been committed in the first half of the tables, and M. Borda thought it necessary to cancel a great number of the pages; and in order to meet the expense thus entailed on him, he was obliged to dispose of an estate which he had lately acquired in his native place. He was also engaged, towards the close of his life, in the measurement of the force of magnetism, and in the calculations of astronomical refraction. His health had been threatened for several successive winters, and he died the 10th of March 1799.

In his manners he was animated and unaffected. He avoided those who sought his acquaintance merely from the vanity of being intimate with a man of talents, whatever pretensions to importance they might derive from their casual relations to general society. He never married; and he was too much absorbed in the pursuit of science to associate with a very extensive circle even of which was taken after a gallant resistance by an English private friends. Though not a man of learning, he was squadron. He was thus compelled to pay a visit to Great not deficient in literary taste; and he was, in particular, a Britain, but was immediately set at liberty upon his parole. passionate admirer of Homer. He seems to have posses-He proposed to the academy in this year (M. Mêm. Ac. sed a considerable share of that natural tact and sagacity Par. 1781), a mode of regulating elections, which was which was so remarkable in Newton, and which we also

Borde discover in the works of Daniel Bernoulli; enabling them, like a sort of instinct, to elude the insurmountable difficulties Bordeaux. with which direct investigations are often encumbered; while Euler, on the contrary, as M. Lacroix most truly observes, seems to have taken pleasure in searching for matter which would give scope to his analytical ingenuity, although wholly foreign to the physical investigations which had first led him to the difficulties in question. It would have been fortunate for the progress of science if some of the most celebrated of M. Borda's countrymen had profited by his example, in studying to attain that unostentatious simplicity which is the last result of the highest cultivation. (Lacroix, in Rapport des Travaux de la Société Philomathique, vol. iv. 8. Par. 1800).

BORDE, Andrew, a physician, jocularly styled by himself Andreas Perforatus, was born at Pevensey in Sussex, about A.D. 1500, and educated at Oxford. After travelling through various parts of Europe and Africa, he settled first at Pevensey, afterwards at Winchester, and finally in London, where he is said to have become a fellow of the College of Physicians, and to have acted in the capacity of physician to Henry VIII. But notwithstanding his success in his profession, he died insolvent in the Fleet prison in 1549. He was the author of several small jocular histories and cheap books, such as formed the light reading of those times. He descended to the arts of a mountebank, making humorous speeches at fairs to attract the people; and from him the term "Merry Andrew" is said to be derived. Wood says that "he was esteemed a noted poet, a witty and ingenious

person, and an excellent physician."

BORDEAUX (the ancient Burdigala), an important commercial city and seaport town of France, capital of an arrondissement of the same name, and also of the department of Gironde. It is situated in the centre of an extensive plain on the left bank of the Garonne, 60 miles from its mouth, in Lat. 44. 50. N. Long. 0. 35. W. Large vessels come up to the town by means of the river, which at its narrowest part here has a breadth of upwards of 2000 feet, with a depth of 16 feet at low, and of 30 at high water. A magnificent bridge of 17 arches, 1534 feet in length, crosses the river. In the old part of the city the streets are narrow and crooked, and the houses ill built; but in the new part the streets are well laid out and handsome, containing many elegant buildings. Among the public edifices of Bordeaux are the theatre, one of the finest in Europe, and seated to hold 4000 persons; the cathedral, a fine Gothic structure, with two elegant spires 150 feet high; the remains of the Palais Gallien, supposed to have been built in the time of the emperor Gallienus; the churches of Ste Croix, St Michael, &c. Bordeaux is the seat of an archbishop, of a national court and court of assize, tribunals of primary instance and commerce, and has a museum, a public library of about 110,000 volumes, picture gallery, botanic garden, exchange bank, public baths, &c. It has also several hospitals and other charitable institutions; several literary societies; a university academy; academy of arts, sciences, and belleslettres; a royal college, school of medicine, normal school, and a school of navigation. The river here describes a semicircle, and is lined by quays for about three miles. The trade of Bordeaux is very extensive, particularly in wines, brandy, plums, almonds, and other fruits. It is greatly promoted by the Languedoc canal, which communicates with the Mediterranean. The wine trade, though still large, has been greatly reduced by the prohibitive system of commercial policy pursued in France. Previous to 1790 the department of the Gironde exported annually above 100,000 tuns of wine to the north of Europe: the export at present is not above 25,000 tuns. In 1842, 497 foreign vessels of 103,461 tons, and 3293 French vessels, of 226,694 tons, entered the port; and 491 foreign vessels of 101,719 tons, and 3038 French vessels of 204.611

tons, departed. There are numerous docks and building yards for vessels of every size, even ships of the line. Its manufactures are numerous, especially tobacco and smuff, brandy, sugar, vinegar, iron and steel goods, chemicals, leather, liqueurs, cottons, woollens, kid gloves, &c. Pop.

(1851) 123,935; of arrondissement, 296,632. The origin of this city dates prior to the conquest of Gaul by the Romans, at which time it was the capital of the Bituriges Vivisci, a powerful Gallic tribe. It is first mentioned by Strabo, who describes it as being a celebrated commercial city. Hadrian made it the metropolis of Aquitania Secunda. In 415 it was taken by the Visigoths, and retaken by Clovis in 509. In 729 it was pillaged by the Saracens, and afterwards suffered much from the ravages of the Normans about the time of the fall of the Carlovingian empire. It was rebuilt by the dukes of Guyenne about the beginning of the tenth century. By the marriage of Eleanora,—daughter of William X., last Duke of Guyenne, to Henry, Duke of Normandy, afterwards king of England,

it came into the hands of the English; in whose possession

it remained till 1452, when it was again united to the French

BOREAS (Bopéas or Boppas), the Greek name of the north wind blowing from the Hyperborean mountains. In mythology, Boreas was the son of Astræus and Eos (Aurora), or of the river god Strymon. He dwelt in a cave on Mount Hæmus, whence he issued and carried off Orithyia, the daughter of Erectheus, king of Attica, by whom he begot Zetes, Calais, and Cleopatra the wife of Phineus, who are therefore called Boreades. During the Persian war the Athenians invoked Boreas, who destroyed the enemy's fleet. In gratitude they dedicated a temple to him; and a festival, called Boreasmus or Boreasmi, was celebrated with banquets in his honour. By the mares of Ericthonius he begot twelve horses of such fleetness, that in passing over the sea they scarce touched the waves. Boreas was represented with wings, white hair, and the tails of serpents instead of feet.

BOREL, PIERRE, a learned physician and antiquary, born at Castres in Languedoc, about 1620. He took his doctor's degree at Montpellier in 1640, and practised with great success in his native city. In 1653 he settled in Paris, having been named counsellor and physician in ordinary to the king; and in 1674 was admitted into the Academy of Sciences. He died in 1689. His works, chiefly on medical subjects, are numerous. The principal are, Historiarum et Observationum medico-physicarum Centuriæ quinque, Castres, 1653, 12mo; Bibliotheca Chimica, Paris, 1654, 12mo; De vero Telescopii inventore, cum brevi omnivm conspiscillorum historia, Hague, 1655, 4to; Hortus, seu Armamentarum Simplicium, plantarum, et animalium ad Artem medicam spectantium, Castres, 1666, 8vo; Observationum Microscopicarum Centuria, Hague, 1656, 4to. He was also the author of several works in French, particularly two treatises on Antiquities, and a discourse on the Plurality of Worlds.

BORELLI, GIOVANNI ALFONSO, the head of what has been called the iatro-mathematical sect,—or that which, misled by the great progress that the application of the mathematics had produced in the physical sciences, attempted to secure the same advantage for medicine, by subjecting to calculation the phenomena of the living economy,—was born at Naples, January 28.1608. He professed his system of iatromathematical philosophy in some of the most celebrated universities of Italy, particularly at Florence and Pisa, where he rose into high favour with the princes of the house of Medicis; but having been engaged in the revolt of Messina. he was obliged to retire to Rome, where he spent the remainder of his life under the protection of Christina queen of Sweden, who honoured him with her friendship, and by her liberality softened the rigour of his fortune. He died of a pleurisy, December 31. 1679. Borelli, more judicious than Bellini, restricted the application of his system chiefly to

Boreas Borelli.

Borgia

Borgog-

Borga Borgia. muscular motions, or to those phenomena of the animal economy which are in certain points subject to the laws of mechanics; and it cannot be denied that it conducted him to the discovery of some principles new in themselves, and directly opposed to the received belief of his time. But his followers, less cautious, wished to generalize the application he had made; and in framing hypotheses, on which time and the return to a sound medical philosophy have done justice, they greatly retarded the restoration of the science. The works of Borelli are, 1. Della Causa delle Febri maligne, Pisa, 1658, 4to; 2. De Renum usu judicium, Strasburg, 1664, 8vo; 3. Euclides Restitutus, 1628, 4to; 4. Apolonii Pergæi Conicorum, libri v. vi. et vii., Florence, 1661; 5. Theoriæ Mediceorum Planetarum ex causis Physicis deductæ, Florence, 1666, 4to; 6. Tractatus di vi Percussionis, Bologna, 1667, 4to; 7. Historia et Meteorologia incendii Æthnei, Reggio, 1669, 4to; 8. De Motionibus naturalibus a gravitate pendentibus, Bologna, 1670, 4to; and, 9. De Motu Animalium, opus posthumum, Rome, 1680, 1681, 4to.

BORGA, or Borgo, a seaport town in Russian Finland, in the laen of Nyland, 28 miles E.N.E. of Helsingfors. It is the seat of a bishop, contains 2138 inhabitants, and carries on trade in linen and in timber.

BORGHESE, a noble Sienese family, one of whom, being elected pope in 1605, assumed the name of Paulo V., after which the family became among the most powerful of the Roman nobility by their union with the Aldobrandini. The late prince in 1803 married Pauline, sister of the Emperor Napoleon, and widow of General Leclerc. This prince sold to his imperial brother-in-law the noble Borghese collection

of antiquities for 13,000,000 francs.

BORGIA, ALEXANDER. See ALEXANDER VI., Pope. Borgia, Casar, a man distinguished both for his talents and his crimes, was the illegitimate son of Rodriguez Lenzuoli, afterwards Pope Alexander VI., and of a Roman lady named Vanozza. At a time when the court of Rome was a school of falsehood and licentiousness; when the frequency of political iniquities had utterly effaced all shame; when treaties afforded no guarantee, and oaths inspired no confidence, Borgia may be said to have systematized crime, and to have carried utter disregard of all ties, human or divine, to an extent previously unknown. He had scarcely completed his studies when he obtained the archbishopric of Pampeluna; and in 1492 his father, who was now pope, made him archbishop of Valentia, and soon afterwards gave him a cardinal's hat. When Charles VIII. of France appeared before the walls of Rome, the pontiff was obliged to treat with him for the preservation of his capital from invasion. The king, who knew the character of the pope, demanded that his son Cæsar should accompany him as a hostage; but scarcely had the French army quitted Rome when Borgia contrived to escape from the camp. In 1497 Alexander bestowed the duchy of Benevento, together with the counties of Terracina and Pontecorvo, on his eldest son, who had already received from the king of Spain the duchy of Gandia. His brother's elevation excited Cæsar's jealousy; and when the duke was murdered about a week after his investiture, public opinion ascribed the deed to the cardinal. By his father's permission he now laid aside the purple, and devoted himself to the profession of arms. He was invested with the honours of his brother, and employed to carry to Louis XII. the papal bull of divorce which that monarch had long desired to obtain. In return for this favour Louis made Borgia Duke of Valentinois, and gave him a pension of 20,000 crowns, with a body-guard of 100 men. In 1499 Borgia married a daughter of King John of Navarre, and accompanied Louis XII. to Italy. He first undertook the conquest of Romagna, and caused the lawful possessors of the land to be treacherously murdered. He was appointed Duke of Romagna by his father in 1501; and he then wrested from Jacopo d'Apiano the principality of Piombino.

In his endeavours to make himself Duke of Bologna and Florence he was unsuccessful. For the conquest of Camerino he demanded soldiers and artillery from Guidobaldo of Montefeltro, Duke of Urbino. Camerino was taken by storm, and Julius of Barona the lord of the city, and his two sons, were strangled. This fate Borgia reserved for all whom he had pillaged. He scrupled not to attain his ends by the vilest treachery; and, by fallacious promises to spare life on the condition of surrender, he ensuared many in his toils. His violence at length aroused the powers of Italy to form a league against him; but he found means to dissolve this alliance by assembling a body of 3000 Swiss, and winning over their troops to his interest by advantageous offers. There now seemed no obstacle to his being proclaimed king of Romagna, of the March, and of Umbria, when Alexander VI. was suddenly cut off on the 17th August 1503, by partaking accidentally of the poison which he and Borgia had prepared for nine newly-elected cardinals, in order to seize upon their possessions. Rorgia likewise suffered severely from the same poison, but by the use of antidotes he recovered. Having obtained possession of his father's treasures, he assembled his troops in Rome, but found himself deserted by his officers, and surrounded on every side by enemies, one of the most bitter of whom was the new pope, Julius II. Borgia was arrested, and sent to Spain, where he was imprisoned by the Spanish court for two years, but at length made his escape through a window, and fled to his brother-in-law the king of Navarre. He accompanied that prince in his expedition against the Castilians, and fell fighting under the walls of Pampeluna, the

seat of his first diocese, March 12. 1507. Borgia may be regarded as an incarnation of whatever is most detestable and infamous among men. Many princes have shed more blood, many have inflicted more terrible vengeance, but the name of Cæsar Borgia is attainted with a surpassing infamy. Others have been hurried on by their passions; but with Borgia everything was the result of cool deliberation. His manners were as dissolute as those of his celebrated sister Lucrezia; yet, like that princess, he was a patron of letters, even produced specimens of poetic talents, and found panegyrists to celebrate his genius and taste. His situation imposed upon him the necessity of temperance, but in this is included everything that can be said in his favour, unless credit be given him for that seductive eloquence of which he was an undoubted master, and which he employed for the purpose of inveigling his intended victims into his toils. It is not without reason, therefore, that Machiavelli, in his Prince, has taken Cæsar Borgia as a model: he could not among men have chosen a hero better qualified to inspire unmitigated horror and detestation.

Borgia, Lucrezia. See Alexander VI., Pope.

BORGO, SAN DONINO, a walled town in the duchy of Parma, fourteen miles N.W. of the city of Parma. It has a fine cathedral and town-hall, and manufactures of silk and linen goods. Pop. 4200.

Borgo, San Sepolero, a town of Tuscany, province of Florence, on the Tiber, fifteen miles N.E. of Arezzo. It has a strong citadel, a cathedral, and numerous churches.

Pop. 4500.

BORGOGNONE, JACOPO CORTESE, so called from Burgundy, the place of his birth, was born at St Hippolite in 1621. He studied at Bologna, where Guido was in full reputation, and was befriended by that great artist, whose mode of colouring he studied with advantage. Cortese was chiefly remarkable for the life and spirit which he imparted to his battle pieces, which he always represented as scenes that he had witnessed. He resided long at Florence, where he acquired a handsome independence by his profession, which he assiduously practised till 1655, when some religious scruples induced him to become a Jesuit monk. Yet even then he continued to employ his pencil on his favourite

Borgoo Boring. subjects, until apoplexy put a period to his life in 1676. Many of his spirited pictures are in British collections, particularly four in the Earl of Derby's residence at Knowsley, two of which are battle pieces, another a Turkish march, and the fourth the overthrow of the host of Pharaoh in the Red Sea.

BORGOO, a large kingdom in the interior of Africa, bounded on the east by the Niger, on the south by Eyeo or Yarriba, on the west by Dahomey, and on the south by Gourma. It is about thirty days' journey in length, and eleven in breadth. It has generally a level surface, though crossed by a considerable range of mountains. The soil is mostly fertile, and tolerably cultivated, producing in abundance corn, yams, plantains, and limes. The cattle are not numerous, but there is a copious supply of all the species of game that prevail in Africa. A considerable inland trade between Houssa and the coast passes through this territory. When Clapperton entered it from Eyeo, he was warned to be on his guard, as the people were the greatest robbers and plunderers in all Africa, and he would run the risk of being stripped of everything he possessed. He found this bad report altogether unjust, and declares, on quitting it, that the people had always behaved honestly, and never robbed him of the slightest article. They were cheerful, obliging, good-humoured, and communicative. The acts of robbery, too frequent in that country, were perpetrated by slaves of the chiefs and governors, who were natives, not of Borgoo, but of Houssa. These persons, in virtue of the service in which they are employed, think themselves entitled to pilfer whatever comes within their reach. The kingdom of Borgoo is divided into the four states of Boussa, Wawa, Kiama, and Niki, the three last of which were visited by Clapperton in his journey through interior Africa. Boussa, remarkable as the scene of the disastrous fate of Mungo Park, holds the first rank, and all the others are considered as in a degree of dependence upon it.

Borgoo, another country of the same name in Central Africa, of which little is known, and that little by hearsay, as it has never been explored by Europeans. It lies to the N.E. of Lake Tsad, about midway on the road to Egypt. It forms a connecting link between the basin of that lake and that of the Nile. It is mountainous; the atmosphere is said to be very pure; its numerous valleys are irrigated by perennial rivers, and are extremely fertile in date trees. It is inhabited by the Uelad Soliman, a well-known powerful Arab tribe. In the latter end of 1851 Dr Barth and Dr Overweg, then at Kuka, determined to visit and explore this interesting region, and set out with a large army despatched by the sheikh of Bornu for the invasion of the countries eastward from Lake Tsad. Unfortunately, however, this army was soon met by the enemy, defeated, and put to flight so suddenly, that Barth and Overweg saved their lives and instruments only by a quick retreat. They consequently did not succeed in reaching Borgoo, which is allied to Bornu.

BORING, generally speaking, is the art of perforating a solid body. In the present article it is proposed to give some account of the boring of Cannon, of Cylinders, of Muskets, of Portland Stone, of Rocks, and of Wooden Pipes.

1. Boring of Cannon is performed by placing the cannon on an axis, which is turned by a very strong power, whilst a steel cutter, in form of a drill, is pressed against the metal, and excavates the cylindrical cavity which is required. Boring may be considered as a branch of the art of turning, which, in general, is the formation of cones, cylinders, and other figures that have an axis, by making a straight line or curve revolve round the axis on which the material is fixed, or by making the material revolve whilst the generating line remains at rest. In turning bodies of no great degree of hardness, and where it is required to take

off only a small portion of the surface at once, a small power is sufficient to put the turning machine in motion; and the longer the edge of the cutter which is applied to the metal is, and the harder the metal, the greater force is required to turn the machine.

Cannon, at first, were frequently made of bars of malleable iron, placed longitudinally, and these bars covered with iron hoops, the whole welded or brazed together. Ordnance of this construction was not sufficiently strong to resist the explosion of the powder, and did not admit of the cylindrical cavity being formed with much accuracy. Its use was, therefore, gradually laid aside, and guns of castmetal were employed. And before the casting of cannon became general, guns of castmetal were reserved for the most important situations; thus the ships of the admiral and vice-admiral alone had cast-metal cannon, the other ships of war being armed with wrought-iron guns only.

Copper, without mixture, has been employed to cast guns, as appears from two large cannon made in the time of Henry VIII., and bearing his name, in the armoury of the Tower of London. But the only two materials now used for cannon are bronze, which is a mixture of copper and tin, and cast-iron. In modern times the use of cast-iron cannon has become more general, as that metal has the advantage of not being softened by the heat of the inflammation of the powder; whereas brass guns, when fired many times in rapid succession, become heated so nearly to the melting temperature of the metal, that the muzzle of the gun droops, and the touch-hole is much enlarged.

The first cannon made of cast-metal were cast hollow, with a cavity as nearly cylindrical as could be executed by casting. The surface of this cavity was then smoothed on a boring machine by steel cutters set in a copper head, and disposed so as to describe a cylinder terminated by a half spheroid. These cutters (in French alezoirs, and the operation alezer) are represented in the French Encyclopedic—planches, Fonte. This method of making guns has long been laid aside on account of the holes and inequalities in the cavity thus formed, and the difficulty of casting the cavity so as that its axis shall coincide with the axis of the piece. Cannon are now always cast solid, and the cylindrical cavity is formed by boring in this solid mass.

The power employed for boring cannon ought to be in proportion to the hardness of the metal of which they are composed, and to the size of the pieces. For the boring of guns of brass, as it is called, that is, a metal composed of ten parts of copper, one of tin, and two of brass, or of these metals in other proportions, a metal softer and more easily bored than cast-iron, horses are sometimes employed as a moving power; but the strong moving powers of water or steam must be had recourse to for boring large guns of castiron, which is the material used for making the largest guns now in use, and is also the hardest substance used in their manufacture. Indeed, some kinds of cast-iron are too hard to admit the action of the borer; and for the making of guns it is necessary to melt pig-iron of different qualities together in order to have a metal that shall possess no more than the required degree of hardness.

The quality of pig-iron is known by the appearance of its surface, but more decisively by the appearance which its fracture presents. To obtain this fracture, a man takes one end of a pig in each hand, and lifting it as high above his head as he can, throws it with force, so that the middle of the pig shall fall across another pig placed on the ground. In this way the pig thrown down is broken. Soft or gray pig-iron, which is the most valuable, breaks with difficulty, and the surface of its fracture is of a gray colour, composed of pretty large crystalline grains. Hard or white pig-iron breaks easily; the surface of the fracture is white, and not sensibly granulated, the grains that compose it being small. The pig-iron here

Cannon.

iron smelted with charcoal of wood has a fracture of a different appearance, sometimes lamellar, like the fracture of metallic bismuth. Formerly guns used to be cast from the blast furnace; that is to say, immediately from the ironstone. This was attended with uncertainty in respect to the nature of the metal; for the nature of the metal given by the blast-furnace varies frequently and suddenly, from causes either unknown, or not under the command of the iron-master. For this reason guns are no longer cast from the blast-furnace, but pig-iron already formed is taken, of such qualities and in such proportions as to form a metal neither too soft nor too brittle and hard for guns. The different kinds of pig-iron thus selected are melted together in a furnace, called in iron manufactories an airfurnace, and by some writers a reverberatory furnace, by the flame of pit-coal; the flame being impelled by a strong current of air produced by the rarefaction of the air in a chimney of thirty or forty feet in height. The column of the atmosphere of which the air in the chimney makes a part being lighter than the unrarefied columns of the atmosphere next it, its equilibrium with these columns is destroyed. The neighbouring columns, therefore, rush through the grate of the furnace, which is the only aperture by which they can attain the bottom of the rarefied column; and they carry the flame of the coal against the pig-iron, which is thereby brought into fusion. From the iron thus fused only one large gun is cast at a time, the furnace not being capable of melting more metal than is requisite for that purpose.

The gun is cast with two appendages, which are to come off before it is finished and ready for use. The one is a square piece beyond the cascabel, for fixing the gun so as to revolve with the axis of the boring-mill; and the other

The head in cast-iron cannon is a mass of cast-iron two or three feet long, and somewhat bell-shaped. It is a prolongation of the mass of metal beyond the muzzle ring, and, in the position in which the gun is cast, the head is the top of the whole mass, the square beyond the cascabel being the lowest part. After the metal has cooled, the upper surface of the head is cavernous, as is the case with the surface that is uppermost during the casting and cooling of any large body of cast-iron. The sides of the cavities in the head are frequently formed of cast-iron crystallized in a fern-leaf form. The intention of the head is to prevent these cavities, which are formed most abundantly at the upper surface of the cooling cast-iron, from forming in the gun itself. But, notwithstanding the precaution of casting the gun with a large head, and of mixing proper kinds of cast-iron in the air-furnace, it frequently happens that small cavities occur in the guns.

Vertical boring.

The gun with its head being cast and allowed to cool, it is conveyed to the boring-mill, where the head is to be taken off, the cylindrical cavity or bore is to be formed, and the outside of the gun is to be turned. Formerly the boring of guns was done in an upright position; the gun being placed above the boring-bar, was fixed in a frame sliding vertically in grooves. This frame was suspended on each side by a block and tackle, and the end of each of the two ropes was wound round a windlass. By turning these windlasses the gun might be raised or lowered, and by this means might be allowed either to press with its whole weight on the boring-bit, or with any part of its whole weight. A figure of this apparatus may be seen in the French Encyclopédie-planches, Fonte. Another vertical apparatus for boring cannon is represented in Rinman, Bergwerks Lexicon, Stockholm, 1789, tab. iv.

The practice which has long been followed in this coun-Horizontal try is to place the gun horizontally in the boring-mill; and boring.

Boring. spoken of is that smelted by the coke of pit-coal. Pig- it is fixed on the axis of the mill by means of the square Boring. piece at the cascabel.

> In a boring-mill constructed by Smeaton, one gun is placed on the horizontal axis of the water-wheel itself, and, consequently, revolves with the same velocity. On this same axis is a toothed wheel with seventy-eight teeth, which works two wheels, one placed on each side of it, and each having twenty-nine teeth. On the axis of each of these a gun is placed; their power is $\frac{1}{27}$ the of the power of the centre wheel. (See Smeaton's Reports, vol. i.) On the axis where the power is least, smaller sized guns are bored; on the axis of the greatest power the large guns are bored. A crane, movable on a vertical axis, with a sweep that extends over all the carriages, with a tackle hanging from its beam, and wrought by a windlass, serves to place the gun on the carriage where it is to be bored, or to remove it from one carriage to another if required; and afterwards, when the gun is bored and turned, the crane serves to remove the gun from the boring-mill.

> The gun, when placed on the machine, has the square at the cascabel fixed in a square iron box (G, Plate CIX. fig. 5) on the axis. This box has a screw passing through each of its sides, and by the operation of these screws the square of the gun is adjusted, centred, and fixed; the chace of the gun is also fixed in a collar N, in which it is to revolve. (The collar in the figure is

represented too near the muzzle ring.)

The axis on which each gun is fixed may be set in gear, or put in connection with the revolving axis of the machine, so as to move round with it; or taken out of gear so as to remain at rest, although the other parts of the machine continue in movement. There are various methods of doing this. One is given by Smeaton in the work above cited. After the gun is fixed on the axis, and before beginning the operation of boring, the head, which has been described above, is cut off near the muzzle ring. For this purpose the gun is set in gear so as to revolve on its axis with the moving power; and a bar of steel, in shape and size like the coulter of a plough, is applied at right angles to the axis of the gun. The narrow side of this bar is sharpened to a cutting edge, so that it has the form of one tooth of a very large saw; and this cutting edge is opposed to the direction of the revolving motion of the gun, and held strongly on to the gun by a screw pressing on the bar; the cutter takes off an angular portion at right angles to the axis, till the cylindrical part connecting the head with the gun is so much diminished, that the head is made to fall off by the blow of a hammer applied on it. In brass guns, cast with a core, the head was sawed off by hand with a blade of steel, whose edge was toothed as a saw, while the sides were toothed as files. See the French Encyclopédie—planches, Fonte.

A great degree of heat is generated by the violent friction of the steel-cutter on the cast-iron during the operation of cutting off the heads of guns. The quantity of this heat has been estimated by Rumford in one of his

Essays on Heat.

After the head is taken off, the workmen proceed to bore the gun. This is done by exposing the revolving gun to the action of a steel-cutter, fixed on the end of a bar, which bar is placed on a carriage, and impelled continually towards the gun. The operation of boring is done on the same axis on which the head was cut off, if the power be sufficient; if not, the gun is removed, by means of the crane, to an axis, where it is made to revolve by a stronger power.

The boring-bar is fixed on a carriage sliding in iron grooves, which are truest when made triangular. The carriage, which, in the apparatus represented at fig. 5, consists merely of the bar on which the rack is, is pressed

VOL. V.

BB; and this pinion works into a rack R. The axis of the pinion has mortised holes in it, through which one end of a lever L is passed; and the other end of this lever is loaded with a weight W, which causes the pinion to propel the carriage and boring-bar towards the gun. In many boring-machines there are two pinions on the same axis, acting on two racks; in others, the carriage is propelled by two upright levers, on the end of one of which acts a weight, hanging from a rope, that passes over a pulley; the lower end of the upper lever acts on the upper end of the lower, whilst the lower extremity of the lower lever presses forward the carriage. This method, which is free from any inequalities that may arise from the teeth of the rack, is figured by Smeaton in his Reports, vol. i. p. 396. Another method of propelling the carriage of the boringbar, is by a screw acting on the end of the carriage. See Meyer in the Transactions of the Academy of Stockholm, 1782, tab. ix.

The boring-bar is a very strong piece of wrought iron, of less diameter than the intended calibre of the piece, in order that the boring dust or shavings detached by the cutter may be got out. The boring bar is increased in diameter near the end, for some inches, see fig. 6, B; in this part there is a superficial groove for receiving the sides of the steel-cutter or bit, which is to be firmly fixed in the bar. The bit T, fig. 6, is made from a rectangular piece of a steel bar, in which the two upper angles are cut off obliquely, so as to form two cutting edges like an obtuse-angled drill; the side of the rectangle, opposite to the point of the drill, is then hollowed out in the form of a pigeon hole; and this hollow fits into and embraces the solid part of the boring-bar, whilst the sides of the pigeon hole fit into the grooves of the bar. The point of this obtuseangled bit is pressed against the revolving metal of the gun, by the force which propels the boring-bar; and the edges coming in contact with the revolving metal, a conical cavity is produced; so that, by taking off successively a multitude of similar shells or shavings, the cylindrical bore, with a conical termination, is formed. The diameter of the pointed bit first used must be less than the intended calibre of the piece, as the boring is to be repeated again at least once, in order to make the internal cylindrical surface as smooth as possible, by taking off any inequalities that have been left by the first cutter. In finishing the bore, a cross bit may be employed. It is a rectangular piece of steel, ground to a cutting edge at each end, and put through a hole in the boring-bar, in which it is fixed. The edges of this cutter, in revolving, describe a cylindrical surface. After the cylindrical surface of the bore is made sufficiently true, and of the required calibre, a bit without a point, and rounded off to the desired curve, is used to form the bottom of the

Some recommend that the boring-bit for cast-iron should have its cutting edges brought to an acute angle, by being filed hollow; but in this case the two edges cannot be brought into one point; for the obtuse-angled edge formed by the thickness of the metal of the bit joins the two cutting edges crossways, and forces itself forwards by being near the centre, requiring, however, a considerable pressure. These hollow-edged bits are not so well adapted to continuance of grinding as the plain ones, but they make amends by their much less frequently wanting sharpening. It does not appear, however, that these hollowedged bits have been found advantageous in gun-boring.

The howitzer appears to have had its origin in Germany. This piece of ordnance, the mortar, and the carronade, in all of which the diameter of the chamber for

Boring forward by a pinion P, whose gudgeons are on a fixed frame the bore, are first bored all through, nearly to the intend- Boring. ed calibre of the chamber, and then that part of the bore that requires it is enlarged.

The cutters in gun-boring become magnetic, in consequence of being continually rubbed in the same direction, so that the boring dust is seen adhering and hanging from their edges when they are withdrawn from the gun.

It is required that the bore shall be a cylindrical cavity whose axis coincides with the axis of the gun: for this purpose, care must be taken to place the axis of the boring-bar, and that of the gun, both in one horizontal line, and it is requisite that these two lines continue in this position during the whole operation of boring. The centring of the boring-bar for this purpose requires to be done by an experienced workman, and an accurately-constructed boring-machine is necessary for the continuance of the right position.

sculptor of Rome.

Whilst on the axis of the mill, the gun has a smooth outer surface given it by turning tools, which are applied in the way usual in turning metals; a wooden gauge, or cut-out profile, of the gun, with its intended mouldings, being applied to know when the turning has been continued to a proper depth. When this is done the gun is taken out of the boring-mill; the square at the cascabel is cut off by the chisel; and the trunions, and other parts which are not susceptible of being turned, are dressed by The cyphers and arms which had been cast the chisel. on the gun are finished by the chisel.

A cannon is said to constitute the ultima ratio regum, the last argument that governments have recourse to; and even this severe kind of argument has sometimes been embellished. Amongst ornamented cannon, the brass threepounder in the Tower, brought from Malta, is a masterpiece; it is covered with carving in a good taste by a

The touch-hole is drilled by stock and bit, or by drill and bow; the drill being propelled by a lever placed on a carriage, movable on wheels. A figure of this apparatus is given in the Encyclopédie—planches, Fonte. Another apparatus for this purpose is figured in Rinman, Bergwerks Lexicon, table xiv. fig. 9, 10. See also Monge, Description de l'Art de Fabriquer les Canons, in 4to, Paris, 1794. This work was published by order of the revolutionary government, and distributed to the iron-masters and founders in different parts of France, for their instruction. It contains, amongst others, figures and descriptions of two kinds of vertical boring machines, of three kinds of horizontal boring machines, of a machine for turning the trunions, of two different machines for boring the touch-hole, of a machine for putting copper boshes in brass guns, and of various instruments for examining and proving guns.

Before the gun is sent off, it is examined and proved in various ways. And first, to ascertain whether the bore is free from holes, an instrument is employed, consisting of several elastic steel prongs disposed in a circle, and with their sharp points turned outwards. This being fixed on a pole, is introduced into the bore of the gun, and drawn to and fro; the points of the prongs press against the sides of the bore, and the presence of a hole is known by one of the prongs getting into the hole, and preventing the instrument from being drawn out directly, unless by the use of a ring that is pushed over the prongs to unbend them.

There is another instrument, composed of a board twice as long as the bore of the piece. Along the middle of the board is a groove proceeding in a straight line. In this groove a button is movable, and on the button, as a centre, are fixed two radii or arms; the two ends of these arms within the gun describe a line on the inside of the bore when the powder is smaller than the diameter of the rest of the button is pushed inwards, whilst the extremities of the

Boring. arms on the outside describe two similar lines on the part of the board that is situate without the bore. In this way the outline of a longitudinal section of the bore is described, and its sinuosities or deviation from the axis are rendered sensible. This instrument is seldom used; it requires to be made by a workman skilled in the construction of mathematical instruments, or in watchmaking.

> A lighted wax-candle is introduced into the gun for the purpose of seeing any defects there may be in the bore, or the light of the sun is reflected into the bore by a mirror. The strength of the gun is proved by firing it with a large charge of powder; and by forcing water into the bore by a powerful forcing pump, the touch-hole being stopped, and also the mouth of the piece, so that water forced in by the mouth cannot return that way.

Cylinders.

2. Boring of Cylinders for steam-engines, and for blowing machines, and the boring of the working barrels of large pumps, and other hollow cylinders in which pistons are to work, is performed by making the steel-cutters describe a cylindrical surface on the inside of the cylinder, whilst the cylinder remains fixed. The first steamengine cylinders in this country were of brass, or of a mixture of copper and tin. This was the case with the cylinder of the steam-engine erected in the early part of the eighteenth century for lifting water from the colliery of Elphinston in Stirlingshire. But since that period the construction of steam-engines, and the manufacture of cast-iron, have been greatly improved; the uses of both have been much extended; and cast-iron has now for a long time been the only material employed in making cylinders for steam-engines, and other large cylinders in

which pistons are to move.

In the boring of cylinders the steel-cutters are fixed in a cutter-head, which revolves with the boring-bar at the same time that it is impelled along the interior surface of the cylinder by a rack, with a pinion moved by a lever and weight as already described. The axis or boring-bar employed for cylinders is a hollow tube of cast-iron, and has a groove passing through it; the length of this groove being proportioned to the length of the cylinder to be bored. The cutter-head consists of two cast-iron rings, the first of which is accurately fitted on the boring-bar, which is turned truly cylindrical, so that this ring may slide along the boring-bar; the second ring is fixed round the first by wedges, its diameter being proportioned to the diameter of the cylinder to be bored; and on its circumference are eight notches to receive the steel-cutters, which are fixed in by wedges. The first ring is fixed on the boring-bar so as to make the whole cutter-head move round with the boring-bar, by means of two small iron bars, which go through notches in the first ring, and pass through the groove of the boring-bar. These small bars have each a round hole in the part which passes through the geometrical axis of the boring-bar; through these round holes there passes a bolt, which forms the end of the rack; a key is put through the end of the bolt, which prevents the rack from being drawn back by the lever and weight; and by this means the rack, impelled by the lever and weight, pushes forward the cutter-head, which is at the same time revolving with the boring-bar; while the connection of the rack and cutter-head being round, and in the axis of motion, the rack is thereby free from the circular motion of the This mode of constructing the boring-bar was invented in the works of Mr Wilkinson, at the time when accurately-bored cylinders came to be required in consequence of Mr Watt's improvements in the steamengine. In the machines about to be mentioned the cutters are made to advance by a train of wheels deriving their motion from the power that turns the boring-bar.

An apparatus of great merit was contrived and describ- Redruth, for new methods of constructing steam-engines

ed in 1802 by Mr Billingsley, engineer of the Bowling Boring. iron-works, near Bradford. (See Repertory of Arts, second series, vol. ii. p. 322.) According to his method the cy-Billings-linder is placed with its axis perpendicular to the horizon. ley's ma-The object of this is, first, that the boring-dust may fall out, and not remain on one side of the cylinder, wearing the cutters; so that in this way the cylinder may be bored through without changing the cutters, by which means a more regular bore is obtained. Secondly, That the cylinder may not deviate from its cylindrical form by its own weight, a deviation which is found to take place in large and slender cylinders when laid on their side; the vertical diameter being then less than the horizontal diameter. A similar loss of shape may happen to cylinders that are improperly wedged and strapped down for the purpose of being bored. In this method the cylinder is fixed with screws by the flanges, where it is most capable of resistance, and the screws are disposed so as to press the cylinder equally all round. Thirdly, That the operation may be sooner completed, which is effected in consequence of less time being employed to fix the cylinder in this method. In the usual mode of propelling the cutters described above, the attendance of a man is necessary to change the position of the bar on the axis of the pinion, and to raise the weight. This attendance is dispensed with in the machine under consideration, the mechanism for propelling the cutters being as follows: A leather strap passing over the boring-bar communicates the revolving motion of the boring-bar to a wheel, which communicates a slow motion by a train of wheels and pinions to an axis, bearing two pinions which work into two racks; and these racks push the boring-head and cutters slowly forward on the boring-bar, at the same time that the boring-head is revolving with the boring-bar. The velocity with which it is required that the cutters shall advance varies as the diameter of the cylinder varies, the moving power remaining the same. And by altering the train of wheelwork, the cutters may be made to advance with any velocity required.

Figs. 1, 2, 3, and 4, Plate CIX., are different views Murray's of the machine for boring cylinders, invented by Mr Murray of Leeds. Fig. 1 is an elevation, and fig. 2 a plan, of the machine. W, figs. 1 and 2, is the spur wheel, deriving its motion from water or steam, and communicating a revolving motion to the boring-bar. The toothed wheel A, fig. 1, moves round with the boring-bar B on which it is fixed; it gives motion through the wheels D and E, and to the screw S, whose threads act on the two racks, which racks are fixed to the cutter-head H, and revolve with it. The velocity with which the cutter-head is impelled along the cylinder depends upon the number of threads of the screw in a given length, and on the proportions of the wheels A, C, D, and E, to each other. By varying the velocity of the screw, the cutter-head may be made to move in either direction up or down the cylinder. F is a pinion whose axis ends in a square, which may be wrought by a key, so as to bring the cutter-head out of the cylinder, or push it home by the hand when that is required. The cylinder is fixed in its bed by screws passing through two iron rings, as represented at fig. 4; and in this way the cylinder is equally pressed in the different parts of its circumference. Fig. 3 is a transverse elevation of the collar in which the end of the bar at A, fig. 1, turns; X is the gudgeon in which the spindle X, fig. 1, turns. In fig. 3 are also seen the two apertures through which the two racks pass. By this machine also the flanges are turned truly plane, so that the lid of the cylinder may fit on exactly.

The patent granted in 1799 to Mr Murdoch, engineer,

patent.

relative to boring. He employs an endless screw, which Murdoch's is turned by the moving power, and works into a toothed wheel, whose axis carries the cutter-head; and this method, he says, produces a more smooth and steady motion than the usual mode of fixing the boring-bar immediately on the axis turned by the moving power.

Another article in Mr Murdoch's patent that relates to boring, is his method of forming the cylinder and steamcase. He casts them of one solid piece, and then bores a cylindrical interstice, by means of a boring-tool, made or a hollow cylinder of iron, with steel-cutters fixed to its

edge, and acting like a trepan.

The chambers of brass pumps, whose diameter does not exceed a few inches, are fixed within iron rings, by means of screws, in the manner described above when speaking of Mr Murray's apparatus. The rings are made accurately cylindrical by turning, as is also the boring-bar. The boring-bar has four cross arms on its outer extremity, to one of which a handle is fixed, whereby a workman makes the boring-bar revolve. The cutter-head is made

to advance along the boring-bar by a screw.

3. Boring the Barrels of Muskets and other SMALL ARMS. Rectangular pieces of iron are forged of a proper length and breadth; these are heated in the fire, and the two long edges, which had been previously thinned off, are welded together on a mandril. The barrel thus formed is fixed by a screw on a carriage that moves in iron grooves; this carriage is propelled towards the boringbar by a rope which passes over pullies, and has a weight hanging from its end. The boring-bar is turned by the power of the same mill that turns the grinding-stones for polishing the outside of the barrels. (See Encyclopédieplanches, Arquebusier; and Rozier, Introduction aux Observations sur la Physique, tom. i. p. 157.) Water is thrown on the barrels whilst boring from a trough placed underneath. After the barrel is bored, the interior surface of the bore is polished by the action of the boringbar. The barrel is tried during the operation, by an iron gauge of an inch and a half in length, and of a diameter equal to the intended diameter of the musket. When the barrel is bored, it is held to the light and looked through, and if it contains any flaw, the place of that flaw is marked on the outside with chalk, and the barrel is put on the mandril again, and the defective place heated and hammered; the workman also examines with a gauge whether the barrel is crooked. When the bore has no flaws, the barrel then undergoes the operation of the grinding-mill, to the effect of polishing its exterior surface.

Rifled barrels are put on a bench twelve feet long. The boring-bar is guided by a matrix or female-screw, whose spiral curve is similar to the spiral of the rifles intended to be made; the boring-bar being fixed to a male-screw, which passes through the female-screw, and fits it exactly. The female-screw is fixed to the bench, and has four threads and as many furrows; and these threads, in general, return to the point of the circumference from which they set out, or make a revolution in the length of two feet. The male-screw, which fits into the female-screw, has at one end an iron bar attached to it, by which it is put in motion; at the other extremity is fixed the boring-bar, which passes through the barrel to be rifled; and the boring-bar has a cutter fixed in it, which forms a spiral furrow in the barrel when the screw is turned by the handle. The number of spiral threads in rifle-barrels is from three to twelve. Sometimes the threads and furrows of the riflebarrel are required to be in straight lines; in which case a straight-lined matrix is used. In order that the threads may be placed at an equal number of degrees of the circumference from each other, the bench is furnished with

Boring. (See Repertory of Arts, vol. xiii.), contains some articles a brass plate, divided in the same way as the plate of the Boring. machine for cutting the teeth of clock-wheels.

4. Boring of Portland Stone, so as to form pipes. Portland That kind of calcareous stone called by geologists oolite, stone. which is quarried for building at Portland, Bath, in the neighbourhood of the city of Paris, and other places, admits of being cut by means of an iron blade, acting as a saw, with sand and water. The more compact limestones and marbles are also cut in this way, but not so easily. The other kinds of stone that can be squared for building, such as sandstone and granite, do not yield to the saw, but are formed into the desired shape by the chisel and hammer. A modification of this mode of working Portland stone consists in forming it into pipes. The method of Sir George Wright, proposed in 1805, is as follows: A hole is drilled through the block of stone, in which a long iron bolt is inserted for the saw to work round as a centre; this bolt forms the axis of the cylinder which is to be taken out, and projects considerably beyond the block at both ends. Another hole is drilled in the intended circumference; and into this the blade of the saw is introduced. The frame of the saw is so disposed, that when it is wrought to and fro, the blade is guided, by means of the centre bolt, so as to describe the intended cylindrical circumference. In this way a solid cylindrical core of stone is detached, and a cylindrical cavity or pipe left in the block. Or the saw may be made to describe a circle without drilling a hole in the centre, by drilling a hole in the circumference, and fixing on the surface of the stone two metallic concentric rings, so that the hole shall be included in the interstice between the rings. The saw is then introduced into the hole, and being worked, it cuts in the circular path formed by the interstice of the rings. See Repertory of Arts, second series, vol. viii.

Mr Murdoch's method, for which he obtained a patent in 1810, is preferable in practice to the above-mentioned method. He employs a cylindrical saw to form the pipe. A plug of wood is inserted in the centre of the intended pipe; this plug receives the lower end of a vertical spindle, longer than the intended pipe; and this spindle is square, with sockets sliding on it. On the upper part of the spindle is a pulley or toothed-wheel, by which the spindle is made to revolve. Near the lower end of the spindle is a wheel, having a circumference like a hoop, three inches broad. The diameter of this wheel is somewhat less than that of the pipe to be bored. It regulates the motion, and fits in the inside of a tube of metal attached to the spindle. The diameter of the tube is nearly equal to that of the intended pipe; but its length is greater by two feet. On the lower edge of the tube is a rim of metal, so much thicker than the tube that the groove cut in the stone by the rim may admit the tube to move freely in it. This rim has an edge like that of a stone-cutter's saw, and in fact performs the office of a saw. The tube is caused to make a reciprocating circular motion round the spindle. There is a cistern placed above the tube, for the purpose of conveying a mixture of sand and water into the cylindrical groove formed in the stone, whilst the machine is working.

Stone pipes, made in the above described way, have been tried for conveying water in London. They were joined by means of Parker's cement, which consists of clay ironstone, burnt, ground to a fine powder, and mixed with mortar. This was the best material that could be got for forming the joints; but these joints cracked and allowed the water to escape, in consequence of the motion of the carriages on the streets under which the pipes were laid, or of the requisite beating down of the superincumbent

5. Boring of Rocks, for the purpose of blasting, has Rocks. already been treated of under Blasting, and we shall only

Muskets.

Borlase.

Boring. add here a description of Hunter's Stone-boring Machine. This implement consists of two parallel bars of steel, bound together at the ends, supporting a traversing carriage, through the centre of which passes a spiral auger attached to a screwed bar; this bar fits into a female screw-clamp above the carriage, and on the upper end is a winch with four cross handles. When the instrument is to be used, it is fixed down to the stone to be pierced by a moveable screw-cramp at each end, and the auger being made to revolve by means of the winch, scoops out at each revolution as great a depth of stone as is equal to the distance which the screw descends. The chips ascend through the spiral channel of the auger, and are thrown off at the top. The peculiar shape of the point of the auger prevents its being rapidly abraded, as it operates by chipping the stone and not by grinding it away. This implement has been used very successfully at various works. At Arbroath harbour, in particular, upwards of 30,000 linear feet were bored for receiving the oaken trenails which were used for strengthening the masonry against the action of the waves. The Arbroath stone is from a bed which underlies the old red sandstone. It is fissile in one plane like slates, and it is this property which fits it for street pavements. It consists of fine grit and schistose debris. (Vide Minutes of Institution of Civil Engineers, vol. ii., p. 146.)

A Mr Talbot of America is reported to have recently invented a boring machine of immense power, which was applied with success to tunnelling through solid rock. have had no means of ascertaining the accuracy of this report, and any notice of it must be deferred for the

present.

Wooden

pipes.

6. Boring of Wooden Pipes is done by means of a long auger, beginning with one of small diameter, and proceeding to employ successively spoon-formed augers of larger diameter. Elm is the wood generally preferred for pipes to convey water. When a tree is to be bored, it is fixed on a carriage, with a rack on the under part. This rack fits into a pinion, the axis of which passes through gudgeons on a fixed frame. On the axis of the pinion is a ratchet wheel, moved by two catches, which derive their motion from the wind or water power that turns the auger; and the pinion is moved in a direction that brings the tree towards the auger. (See a figure in Belidor, Architecture Hydraulique, i. 1, 341.) This apparatus is the same as the one employed in sawmills. Wooden pipes are frequently bored by an auger having at its outer end a wooden drift or handle, which is put in motion by the workman. The trees are placed on tressels, and there are also tressels of a convenient height that support the auger; there is also a lathe to turn one end of the tree conical, so as to fit into a conical cavity in the end of the adjoining tree, and thus form a water-tight joint. The end of the tree which receives the adjoining pipe within it has a surface at right angles to the axis of the pipe. Into this surface is driven an iron hoop, the diameter of which is some inches greater than the diameter of the aperture of the pipe. This precaution prevents the tree from splitting when the conical end of the next tree is driven home. When the tree is crooked, a bore is driven in from each end, and the two bores meet, forming an angle. An auger whose stalk is formed spirally for some way up is figured in Bailey's Machines of the Society of Arts. The object of this is that the chips may be delivered without taking the auger out of the hole.

A patent was granted in 1796 to Mr Howell, coalmaster,. of Oswestry, for boring wooden pipes by a hollow cylinder made of thin plates of iron, about an inch less in diameter than the hole to be bored. To one end of this cylinder is fixed a flange about a quarter of an inch in breadth, one part of which is divided, so that, being constructed of steel, it forms a cutter. The object of this method is to bore out a solid cylinder of wood, capable of being converted into a

smaller pipe, or of being applied to some other use in car- Borissov pentry. (Repertory of Arts, vol. ix.) This kind of borer is like the trepan, which is a hollow cylinder of steel, sawtoothed on the edge, and, when made to revolve rapidly on its axis in the hand of the surgeon, saws or bores out circular pieces of the flat bones of the head. (w. A. C.)

BORISSOV, a town of European Russia, government, and 40 miles N.E. of the town, of Minsk, on the left bank of the Berezina. It is only memorable for the disastrous passage of the Berezina effected in the neighbourhood by the remains of the French army on its retreat from Moscow.

BORJA, a town of Spain, province of Zaragoza, the

chief place of a partido of the same name, on the confines of Navarre and Castile. Pop. 4239, chiefly engaged in agriculture. BORKUM, an island of Hanover, on the coast of East Friesland, situated between the mouths of the East and West Ems. It is about twelve miles in circumference, and

so low in the middle that it is separated into two parts at high water. A considerable proportion of the inhabitants consists of seafaring people, and the remainder draw their support from the rearing of cattle, or in picking up the fragments of vessels wrecked on their coast. It has a governor, a Calvinistic minister, and a schoolmaster. The spire of the church, which serves as a lighthouse, is in Lat.

BORLACE, DR EDMOND, an eminent physician and English writer, was the son of Sir John Borlace, who was master of the ordnance, and one of the lords justices of Ireland in 1643. He studied in Dublin College, and afterwards at Leyden, where he took the degree of doctor of physic. He practised with success at Chester, and was incorporated doctor of the faculty in the university of Oxford. Among other works he published the following:—The Reduction of Ireland to the crown of England, London, 1675, 8vo; The History of the Irish Rebellion, London, 1680, 8vo; Brief Reflections on the Earl of Castlehaven's Memoirs, London, 1682, folio. He died about 1682.

BORLASE, WILLIAM, a learned antiquary and naturalist, born at Pendeen in Cornwall, of an ancient family, Feb. 2. 1696. He was educated at Exeter College, Oxford, where he took his degree as master of arts. In 1720 he was ordained as priest; instituted in 1722 to the rectory of Ludgvan in Cornwall; and in 1732 was presented to the vicarage of St Just, his native parish. In the parish of Ludgvan are rich copper works, abounding with mineral and metallic fossils, of which he made a collection, and thus was led to study at large the natural history of the county. In 1750 he was admitted a fellow of the Royal Society; and in 1753 he published in folio, at Oxford, his Antiquities of Cornwall, a second edition of which was published at London, 1769, with the title of "Antiquities, Historical and Monumental, of the County of Cornwall; consisting of several essays on the ancient inhabitants, Druid superstition, customs, and remains of the most remote antiquity in Britain and the British isles, exemplified and proved by monuments now extant in Cornwall and the Scilly Islands; with a vocabulary of the Cornu-British language." next publication was Observations on the ancient and present state of the islands of Seilly, and their importance to the trade of Great Britain, Oxford, 1756, 4to. In 1758 appeared his Natural History of Cornwall, Oxford, folio. He presented to the Ashmolean Museum a variety of fossils and antiquities which he had described in his works; for which, and similar benefactions, he received the thanks of the university, and the degree of LL.D. He died Aug. 31. 1772, at the age of seventy-seven, leaving two sons. Besides his other literary connections, he had a particular correspondence with Pope; and there is still extant a large collection of the poet's letters to Dr Borlase. Besides the

Born.

Bormio Born.

to the Philosophical Transactions.

BORMIO, a town of the Austrian kingdom of Lombardy, in the province of Valteline, 29 miles N.E. of Sondrio. It is situated at the foot of a lofty hill of the same name, on the left bank of the Adda, is well built, and contains about 2000 inhabitants. Long. 9. 51. E. Lat. 46. 28. N. In the vicinity are the celebrated Bagni di Bormio,

BORN, IGNATIUS, BARON VON, counsellor in the aulic chamber of the mint and mines at Vienna, an eminent mineralogist and metallurgist, was born of a noble family, at Karlsburg in Transylvania, in 1742. He was educated in a Jesuit college at Vienna, and afterwards entered into that order, which, however, after sixteen months, he quitted. He then studied law at Prague, and afterwards travelled into Germany, Holland, and France. On his return to Prague

he engaged in the study of mineralogy.

The mines in the dominions of the house of Austria support a numerous population. Idria produces mercury; Bohemia, tin and cobalt; and the other metals are obtained in sufficient abundance, not only for the home supply, but also for export. Maria Theresa did much for the regulation of the mines; and, with a view to diffusing the knowledge of mineralogy amongst the nobles, she appointed lecturers on that science in the universities. The administration of the revenue arising to government from this source is conducted by a board of managers, overseers, assayers, and other officers, who are instructed in metallurgy and mineralogy, and reside at the mines. The operations of these functionaries are under the control of the aulic chamber of the mint and mines at Vienna. An administration thus constituted offers a field of some preferment; and Von Born was received into the department of the mines and mint at Prague in 1770.

About this time he met with an accident which nearly proved fatal. In the course of a mineralogical journey through Transylvania, he came to Felso-Banya, where the gangue is rendered brittle and detached from the rock by exposing it to the flames of wood heaped up in the mine and set on fire. Having gone into the mine soon after the combustion had ceased, whilst the air was hot, and charged with arsenical vapour, he was deprived of sensation for fifteen hours, and long afterwards continued to suffer from a cough and general pain. Some time after this accident he was af fected with violent colics, which a large dose of opium removed; this was succeeded by a numbness of the lower extremities, and lameness in the right leg. In the latter part of his life he was deprived of the use of both legs. These calamities, however, did not repress the activity of his mind. One of the chief objects of his exertion was to introduce amalgamation in Hungary, in place of smelting and cupellation, for extracting silver from the ores. At this time he published his book upon the subject, in which he gives the chemical theory of operation, and describes the method he had adopted at Schemnitz. Von Born met with much opposition in his attempts to introduce amalgamation. After he had succeeded in getting silver from the ore publicly at Vienna, his detractors endeavoured to prove that the process was inferior to that already in use: and when at last his process was tried successfully in the great way by orders of Joseph II. at Schemnitz, his opponents shrugged up their shoulders, saying, "It is only the old Spanish process of amalgamation." The emperor ordered that his method should be employed in some of the mines belonging to government, and that he should receive a third part of the savings arising from the improvement during the first ten years, and four per cent. of this third part of the savings for the next twenty years.

Von Born was a satirist, though his attempts in that walk were not particularly successful. The Staats Peruche, a

works above mentioned, he contributed many curious papers tale published without his knowledge in 1772, and an attack on Father Hell, the Jesuit, and king's astronomer at Vienna, are two of his satirical works. The satirical description of the Monastic Orders, written in form of an academic inaugural dissertation, entitled Monachologia, is generally ascribed to Von Born. In this piece the monks are described in the technical language of natural history; but it is supposed that he was assisted by Professor Herman of Strasburg, the author of the very ingenious work on the mutual affinities of animated beings, entitled Tabula Affinitatum Animalium Commentario illustrata. (Of this clever work a new edition, with additions and illustrations, was published in Edinburgh, 8vo, 1852.)

Von Born was well acquainted with Latin, and the principal modern languages of Europe. He also possessed information in many branches of science not immediately connected with metallurgy and mineralogy. He took an active part in the political changes in Hungary. After the death of Joseph, the diet of the states of Hungary passed a great many acts, rescinding the innovations of that scheming ruler; and it conferred the rights of denizen on several persons who had been favourable to the cause of the Hungarians, and, amongst others, on Von Born. At the time of his death in 1791, he was employed in writing a work entitled Fasti Leopoldini, probably relating to the prudent conduct of Leopold II., the successor of Joseph, towards the Hungarians.

Von Born lived in splendour, and his house at Vienna was resorted to by scientific men of all nations. It is likely that his profits from the process of amalgamation were not considerable, as at his death his affairs were in a state of insolvency. His family consisted of a wife and two daughters, who survived him. (See Townson's Travels in Hungary; and Pezzil, Ostreich Biographien, 1792.)

The following is a list of his principal published writings,

and of the works of others which he edited.

Lythophylacium Borneanum, 1775, 8vo. This is a catalogue of his collection of minerals, which he afterwards sold to Mr Greville. It now forms a part of the magnificent Greville collection in the British Museum. Index rerum naturalium Musai Casarei Vindo-bonensis. Pars I. Testacea. Vindob. 1778, fol. maj. This splendid volume contains the description and figures of the shells in the museum at Vienna. On the Amalgamation of Ores containing Gold and Silver, published in German, 4to, 1786. It has been translated into English by Raspe. Catalogue méthodique et raisonné de la Collection des Fossiles de Mademoiselle Eleonore de Raab, 8vo, 1790. Poda's Description of the Machines used in the Mines of Schemnitz. edited by Von Born. Ferber's Letters from Italy, written to and edited by Von Born. Ferber, in return, published the lotters addressed to him by Von Born, under the title of Briefe über mineralogische gegenstande auf seiner reise durch das Temeswarer Bannat, Sie-benburgen, Ober und Nieder Hungarn. Frankf. 1774. There is an English version by Raspe, and a French one by Monnet. Some papers in the Abhandlungen der Böhmischer gesellschaft den Wissenchaften. Several papers in the Transactions of a Private Society at Prague, for the improvement of mathematics, natural history, and the civil history of the country. Von Born published an annual periodical work in German, entitled the Philosophical Transactions of the Masons' Lodge of Concord at Vienna, of which institution he was the founder and patron. He was also a zealous member of the Society of Illuminati; and when the Elector Palatine of Bavaria suppressed the masonic societies in his dominions, Von Born who was a member of the Academy of Sciences at Munich, on being required to declare whether he would withdraw from the masonic societies, resigned his place in the academy. He wrote some articles in the German work published by Trebra, mine-director at Zellerfeld in the Hartz, entitled A System of Instruction in the Art of Working Mines, 4to; also Observations in support of the Metallization of the Alkalies, in Crell's Annals, 1790, 1791. Ruprecht and Tondi thought at that time that they had reduced the alkalis and barytes to a metallic state, by the heat of a furnace urged by bellows; but it was afterwards found that the metallic substance thus obtained was phosphate of iron, proceeding from their crucibles and fluxes. The honour of obtaining this result was reserved for Sir Humphry Davy. Relatio de Aurilegio Dacia Transalpina, 1789, in the Nova Acta Academice Natura Curiosorum, tom. viii. p. 97. This is an account of the method employed in Transylvania in collecting gold from the sand of the rivers. (W. A. C.)

Borneo.

BORNEO, or, as it is called by the natives Bruné, an island forming part of the great East Indian Archipelago, and, next to New Holland, which may be considered as a species of continent, the largest in the known world. It reaches from about 7° north to 4° south latitude, and from 109° to 118° east longitude. Its length may be estimated at 750 miles, its greatest breadth at 600, and its average breadth at 350. Its area has been calculated by Baron Melville of Carnbee at 12,745 geographical square leagues. It exhibits the usual insular structure, a mass of lofty mountains in the centre, sloping gradually down to level and alluvial tracts along the sea shore. It is in every part intersected by fine rivers, many of them navigable to a considerable distance from the sea. The interior of Borneo is covered with immense forests, filled with wild animals, particularly orang-utans. A great part of the coast is marshy, so that it is in portions only that it displays the exuberance of tropical fertility. Of all the East Indian islands, Borneo ranks lowest as to civilization and improvement. Nothing, perhaps, has tended so powerfully to check its progress as the solid and unbroken form of its coasts, destitute of those large bays or inland seas which have always proved the nursery of commerce.

The Portuguese discovered Borneo in 1526, though, from the superior wealth promised by the Spice Islands, it attracted comparatively little attention. Yet they, as well as the Spaniards, the Dutch, and the English, formed establishments on different parts of the coast; but the small force defending them, and the fierce animosity of the natives, made their tenure generally of very short duration. The physical structure of Borneo, the vast forests, mountains, and jungles of the interior, obstruct communication between the different parts of its coast, as completely as if an extent of sea had intervened. It is thus split into a number of petty districts, entirely detached from each other, and which cannot be satisfactorily described, unless in detail.

Borneo Proper occupies the northern coast, and is reckoned a state of great antiquity. The soil is comparatively fertile, supplying rice sufficient for the consumption of the inhabitants, as well as most of the camphor for which the island is celebrated. The city, called also Borneo, is built upon alluvial ground, about ten miles above the mouth of the river of the same name. It is compared to Venice; canals are conducted through every street, and all business is conducted in boats, usually rowed by women. The houses are built upon posts, and ascended to by ladders. The river is navigable for large vessels considerably above the town; but there is a bar at its entrance, over which there is scarcely a depth of seventeen feet at high water. The sultan is treated with those marks of peculiar respect which in this part of the world usually indicate an ancient dynasty; but the chiefs or pangerans exercise great power in the state. The commerce of this city and district is almost entirely engrossed by the Chinese, who bring annually from Amou four or five junks, of about 500 tons burden. As the neighbourhood abounds in excellent timber, they frequently build their junks here, and carry them away loaded with the commodities of the country. Since the settlement of Sarawak by Sir James Brooke, in the neighbourhood of this state, it has some communication with the English.

On the eastern coast of Borneo, Mangedava and Pappal are populous, fertile. and well-watered districts. Malloodoo possesses these advantages in a still superior degree, and grows also a large quantity of rattans. Tiroon produces sago in abundance, and birds' nests more copiously than any other part of the Eastern Archipelago. None of these states, however, are much frequented by or known to Europeans. The chief state on the eastern coast is Passir, situated about fifty miles up a river of the same name. This district is very low and flat; and, were it not cooled by the sea breezes, would be intensely hot. Being marshy and filled with woods, it is extremely unhealthy. The town is said not to contain above 300 wooden houses, which are built along the river. The sultan has a palace and wooden fort along the northern bank. The people of Passir have an extremely bad reputation as to their conduct in mercantile transactions. They use false weights

and measures, manufacture counterfeit articles, and embrace, in short, every opportunity of cheating that offers. The English East India Company made an attempt, in 1772, to establish a factory here, but it did not succeed.

Banjar Massin is the principal state on the southern coast of Borneo; and, like the others, it owes its prosperity to a large river, on the banks of which it is situated. This river is five or six fathoms deep; but, unfortunately, the bar does not allow above twelve or thirteen feet of water, and requires the aid of the tide to produce even that depth. Ships, however, may anchor in the port of Tombangou or Tombornio. near the mouth of the river, where they are well supplied with water and provisions. See Banjanmassin. The sultan resides at Martapura, about three days' journey up the river, to which place he is attached by the circumstance of its being an uncommonly fine hunting station. The district of Banjar produces gold and diamonds, both of superior quality to those found in other parts of the island. Pepper is so abundant that, in a commercial view, it may be considered as the staple commodity. The iron is very excellent, and peculiarly fit for steel; though Dr Leyden asserts that the inhabitants do not them

selves understand the art of manufacturing it.

Succadana, or, as Dr Leyden calls it, Sacadina, was once the most powerful state on the western coast of Borneo. The Dutch began to trade there in 1604, but they soon afterwards attached themselves, in preference, to Sambas. In 1623 they abandoned their factory at Succadana. In 1786 they united with the sultan of Pontianak in an expedition against this place, which they took and entirely destroyed. It appears to have been since rebuilt, but is entirely in the hands of the Malays, and scarcely ever visited by Europeans. Pontianak is a state of very recent origin, but it now exceeds in wealth and power all others upon the western coast of Borneo. This distinction it owes to the wisdom of the Arab prince by whom it was founded. He renounced from the first the pernicious policy, almost universal in these petty states, of embarking in trade, and monopolizing its principal articles. He confined himself to his proper functions of dispensing justice and securing protection to all, of whatever country or religion, who resorted to his dominions. Under this salutary policy Pontianak soon rose to be the greatest emporium in those seas. It is situated on a large river, formerly called Laua, and the country behind produces diamonds the most abundantly of any district in Borneo. The Dutch established a factory here in 1776, and maintained ever after a good understanding with the sultan. In 1813, after the British force had taken possession of Batavia, that prince, dreading an attack from Sambas, solicited the protection of a British garrison, which was immediately sent: and he afterwards assisted our troops in the reduction of Sambas. Momparwa, situated a little to the north of Pontianak, is the best market for opium upon this coast. The city lies nineteen miles up the river, the entrance of which is obstructed by a bar and by several small islands. This is probably the same district called Mattan by Dr Leyden, who says that the king possesses the finest diamond in the world, for which a high price was offered by the Dutch, which he refused to accept. Sambas is situated about thirty miles up the river of the same name. Like most other towns in Borneo, it is built of timber and bamboos, and raised by stakes above the swampy foundation. Sambas has always been a powerful state, but for some time past has devoted itself so entirely to piracy as to render its existence scarcely compatible with that of its civilized neighbours. Upon this principle the British, in 1812, undertook an expedition against it; but they were repulsed with great loss in the attack, and suffered still more from the malignant influence of the climate. In the following year, however, a new expedition was undertaken under Colonel Watson, who, on the 3d of July, carried the fort by storm, and obliged the rajah to retire into the interior of his dominions.

Besides Sambas and Pontianak, the Dutch government claims possession of all the coast to the river Roti on the east, including the whole of the southern half of the island. With the exception of a few years, the possession of this extensive country has been in the hands of the Dutch since 1787, but they have done very little either to promote the civilization of the natives, or to develop the resources of the island. They reckon the population of the residences of Sambas and Pontianak, their possessions on the west, at 590,100, and by census made in 1836, 1837, and 1838, they calculate the population

Borneo.

in their dependencies on the south and the east, including Banjarmassin, Mandawa, Sampet, Roeti, &c., at 736,600; in the islands along the coast at 22,000; making the total population of the states dependent on the Dutch government 1348,700.

On a general view of the state of culture and civilization in Borneo, Mr Hamilton estimates the population at 3,000,000, which we should suppose to be rather above than under the truth. The interior is entirely occupied by a native race, called variously, according to the parts of the island which they inhabit, Dyak, Idaan, and Tiroon. Those who subsist by fishing are commonly called Biajoos. The appellations of Horaforas and Maroots have also been applied to these races. The whole may be considered as one, almost savage race, and nearly similar to that which occupies the interior of Sumatra. Some, indeed, cultivate the ground, some display considerable industry in fishing, and a few employ themselves in collecting gold; but their institutions in general indicate the very rudest state of human society. It has been strongly asserted that they devour the flesh of their enemies; an assertion not noticed by Dr Leyden, and which has in many instances been made without foundation. All accounts agree, however, as to the existence of another truly savage custom, by which every man is debarred from the privilege of matrimony till he has, with his own hand, cut off the head of an enemy. Those, therefore, who are desirous of entering into that state form themselves into what they call head-hunting expeditions. They make an inroad into the territories of a neighbouring tribe, and, if their strength appear sufficient, endeavour to effect their object by force; if otherwise, they conceal themselves behind thickets, till an unfortunate individual passes, whom they can make their prey. Some are also said to immolate human victims on the altars of their divinities.

The inhabitants of the towns along the coast consist chiefly of that race so universally diffused throughout the Indian islands under the name of Malays. This name, to a European ear, has usually suggested every extreme of perfidy and atrocity. We have perused, however, a very different estimate of their character, formed by an intelligent gentleman, who spent several years in this part of India. He describes them as honest, frank, simple, and even gentle in their manners, decidedly superior, in a moral view, to the degenerate Hindus. The sanguinary deeds which have exposed them to so much reproach he ascribes to a proud and almost chivalrous sense of honour, which makes them regard blows, or any similar personal insult, as an offence only to be expiated by blood. The coarse and unfeeling treatment which they often experience from Dutch and Chinese masters drives them to these dreadful extremities. Piracy, however, is a vice of which this race cannot be acquitted; and the western coast of Borneo, situated on the great naval route to China, may be viewed as the grand field for its exercise. To a poor and hardy race, who see half the wealth of Asia passing along their shores, the temptation is almost irresistible. Like the Arabs, they have formed for themselves a code of morality, in which plunder is expunged from the list of vices. Yet, though individually brave, they possess no skill or discipline which could render them formidable to the crew of a European vessel. The cowardice of the Lascars, by whom Indian trading vessels are usually navigated, is the only circumstance which has made our trade suffer so severely from their ravages.

Next to the two classes above enumerated, the most numerous are the Chinese. These are considered as the most valuable subjects whom an uncivilized state can receive into its bosom. The difficulty of finding subsistence in their own country has led them to emigrate in vast numbers into Borneo. Nothing, perhaps, except the law which prohibits females from leaving the empire, could have prevented this almost unoccupied island from being entirely filled with a Chinese population. From this circumstance, however, the Chinese colonists are composed entirely of men in the vigour of life, and of the

most enterprising and industrious character. Their chief settlement is at Sambas, on the western coast, where the numbers cannot be estimated at less than 36,000, composing a sort of independent state. Their almost sole occupation is that of extracting the gold which abounds upon this coast. It is found in alluvial soil, and is purified by the simple process of passing a stream of water over the ore. The processes employed for this purpose are daily improving; and the annual yield is calculated at about half a million sterling.

The commerce of Borneo, though not equal to its extent and natural capacities, is by no means inconsiderable. Gold is its principal export. Mr Milburn estimates the annual quantity exported at 200 peculs, or 26,000 lb. avoirdupois, which would coin into upwards of 900,000 guineas. Like some other commodities, it is divided, by a grotesque scale, into three kinds, called the head, the belly, and the feet; the first being the best, and the two others gradually diminishing in value. Camphire is exported to the extent of thirty peculs (3990 lb.), all to China, where it is more esteemed than that of Sumatra. The singular Chinese luxuries of biche-de-mer or sea-slug, and edible bird-nests, are found in Borneo, as over all the Indian Archipelago. Pepper to a considerable amount, canes and rattans of various descriptions, sago, and a little tin, complete the list of exports. The chief import is opium to a very great extent, with piece-goods, hardware, coarse cutlery, arms, and toys. By far the greater proportion of the trade is in the hands of the Chinese.

The enterprise of one man, James Brooke, has within the last few years directed increased attention to this interesting region.

In 1838 Mr Brooke fitted out with his own funds a schooner of 142 tons, for the purpose of exploring the shores of Borneo. He had previously sailed in the Chinese seas, and was deeply impressed with the importance of the magnificent islands to the S.E. of the Straits of Malacca, and conceived the design of reclaiming them from the piratical tribes whose prahus infest the surrounding waters. His first object was to obtain more accurate knowledge of the geography and condition of the islands. He arrived at Sarawak on the N.W. coast of Borneo, in August 1839, and was well received by Rajah Muda Hassim, the uncle of the then reigning sultan of Borneo, and under him the governor of Sarawak. Hassim was then engaged in a war with his rebellious subjects. After remaining some time at Sarawak, making himself acquainted with the country, Mr Brooke sailed for Singapore, but soon returned. The civil war still raging, Muda Hassim solicited his assistance, offering him the government of Sarawak if he succeeded in putting down the rebellion. Mr Brooke joined the rajah, and having compelled the rebels to surrender, he was then formally instituted rajah of Sarawak, with the usual native ceremonies.

This appointment was ratified by the sultan, and the amount of revenue to be paid by Mr Brooke, as rajah of Sarawak, to the sultan of Borneo, settled at 2500 dollars annually.

The wise and vigorous rule of the new rajah was soon visible in the increasing prosperity of his subjects. They were, however, cruelly harassed by the numerous pirates by whom they were surrounded. At the conclusion of the Chinese war in March 1843, H.M.S. Dido, under Captain Keppel, cruising in the straits of Malacca, inflicted a severe chastisement on the pirates. In February 1845 Captain Bethune arrived at Sarawak with despatches from the British government, appointing Mr Brooke Her Britannic Majesty's regent in Borneo. In 1847 it was resolved by the British government to take possession of the small island of

¹ In 1844 the Hon. Capt. Erskine Murray, with two vessels, entered on a trading expedition to Tanganon, the capital of the Sultan of Coti, which lies on the east coast of Borneo, on the river of the same name. The first large town, Semerindon, near the mouth of the river, is inhabited entirely by Bugis, the most bloodthirsty nation of all the tribes of the Archipelago. Passing this, he reached Tantions for the seizure of the span and making preparations for the seizure of the ships and destruction of the crews. With difficulty the two vessels made their escape from the batteries on bimself was killed.

Borneo.

Labuan, lying to the north of the town of Borneo, and the N.W. of the island, and which had been ceded by the sultan to Great Britain. This was occupied with the view of forming a convenient naval station between the East Indies and China. Sir James Brooke was appointed governor of this colony, and took possession on the 2d October 1848. Endeavours were made to induce the sultan to co-operate in the suppression of piracy, but he was either insincere or unable to induce his subjects to relinquish their cruel practices. In August 1845 Admiral Sir Thomas Cochrane, with a considerable force, came to demand reparation for the detention of two British subjects. He proceeded against a strong body of pirates who occupied a fortified position at the head of Maludu Bay, and totally destroyed their works and the town. This lesson, however, had no lasting effect on the sultan of Borneo; he resolved to take vengeance on his two uncles, Muda Hassim and Bundureen, who advocated the abandonment of piracy. He treacherously attacked them both during the night in their own houses, and murdered them and their families.

Sir Thomas Cochrane in the Spiteful, accompanied by Sir James Brooke, ascended the river to Borneo to demand an explanation from the sultan, and after destroying the forts and batteries on the river took possession of the town, which was found entirely deserted.

The people, however, soon returned, but the sultan fled into the interior. After remaining eleven days in the city without being able to compel a satisfactory arrangement, Sir T. Cochrane, with the view of procuring at least a temporary security to those who were favourable to the British, left a proclamation to be delivered to the sultan on his return, showing how completely he and his people were at the mercy of the British; offering to live with him at peace, but, at the same time, threatening him with condign punishment should he again evince hostility to Great Britain.

All these lessons seem to have been lost on the piratical Dyaks, but a much more severe chastisement awaited them. When Rear-Admiral Sir F. A. Collier was stationed at Sarawak in August 1849, information was received that a very large piratical flotilla, consisting of upwards of 100 prahus, averaging 35 men each, had passed the entrance of the Raluka from the Sarebas, with the intention of attacking Sareki, a town on the Rejang. The admiral and Sir James Brooke concerted a plan for intercepting them in their progress, which was completely successful; the piratical flotilla was almost entirely destroyed, about 500 men killed, and a larger number are supposed to have perished in the jungle.

Sir James Brooke, while acting as governor of the British colony of Labuan, retains his dignity and rights as rajah of Sarawak, from which he considers himself entitled to draw such revenue as is consistent with the prosperity of his domains. He holds the monopoly of antimony in his own hands, and his income from all sources is about L.6000 a-year; but this, as he says in a letter to his friend J. C. Templer, even in addition to his private fortune, is small when opposed to the numerous calls upon it; and is all laid out to advance the good of the country.

The inhabitants of his province of Sarawak he calculates at 12,000 in the town, and from 12,000 to 15,000 in the country, besides from 3000 to 4000 Malays along the coast.

"Sarawak," says Sir James Brooke, "extends from Tanjong Datu to the entrance of the Samarahan river, a distance along the coast of about sixty miles E.S.E., with an average breadth of about fifty miles. It is bounded to the westward by the Sambas territory—to the southward by a range of mountains which separate it from the Pontianak territory of Sadony. Within this space there are several rivers and islands besides the river of Sarawak. There are two navigable entrances to this river, and numerous smaller branches for boats, both to the westward and eastward; the two principal entrances combine at about twelve miles from the sea, and the river flows for twenty miles into the interior, in a southerly and westerly direction, when it again forms two branches—one running to the right, the other to the left hand, as far as the mountain range. Be-

sides these facilities for water communication, there exist three other branches from the easternmost entrance, called Moratabas, one of which joins the Samarahan river, and the two others flow from different points of the mountain range. The country is diversified by detached mountains, and the mountain range has an elevation of about 3000 feet. The aspect of the territory may be generally described as low and woody at the entrance of the rivers. except a few high mountains; but in the interior, undulating in parts, and presenting fine level plains. The climate may be pronounced healthy and cool, though during the six months from September to March a great quantity of rain falls; the thermometer stands generally about 78°, never above 85°. The more serious maladies of tropical climates are very unfrequent; the only complaints to which we have been subject are rheumatism, colds, and ague. The soil and productions of this country are of the richest description, and it is not too much to say, that within the same given space, there are not to be found the same mineral and vegetable riches in any land in the world. The soil of the plains is moist and rich, and calculated for the growth of rice, for which purpose it was formerly cleared, and used until the distractions of the country commenced. From the known industry of the Dyaks, and their partiality to rice cultivation, there can be little doubt that it would become an article of extensive export, provided security were given to the cultivator, and a proper remuneration for his produce. The lower grounds, besides rice, are admirably cal-culated for the growth of sago, and produce canes, rattans, and forest timber of the finest description for ship-building, and other useful purposes. The Chinese export considerable quantities of timber from Sambas and Pontianak, particularly of the kind called Balean by the natives, or the lion wood of the Europeans; and at Sarawak it is to be had in far greater quantity, and nearer the place of sale. The undulating ground differs in soil, some portions of it being a yellowish clay, while the rest is a rich mould; these grounds, generally speaking, as well as the slopes of the higher mountains, are admirably calculated for the growth of nutmegs, coffee, pepper, or any of the more valuable vegetable productions of the tropics. Besides the above-mentioned articles there are birds'nests, bees' wax, and several kinds of scented wood in demand at Singapore, which are all collected by the Dyaks, and would be collected in far greater quantity, provided the Dyak were allowed to sell them.

"Of the principal riches of the country, there are diamonds, gold, tin, iron, and antimony ore; and when the country is explored by men of science, it may be expected that its mineral wealth will be found more abundant. The quantity of gold yearly procured at Sambas is moderately stated at half a million sterling. The most intelligent Chinese are of opinion that the quantity got here exceeds the quantity at Sambas, and there is no good reason to suppose it would fall short of it, when once a sufficient Chinese population is settled in the country. Antimony ore is a staple commodity, which is to be procured in any quantity. Tin is said to be plentiful, and the Chinese

propose working it. "In describing the inhabitants I feel sure that their sufferings and miseries will command the interest and sympathy of every person of humanity, and that the claims of the virtuous and most unhappy Dyaks will meet the same attention as those of the African. And these claims have this advantage, that much good may be done without the vast expenditure of lives and money which the exertions on the African coast yearly cost, and that the people would readily appreciate the good that was conferred upon them, and rapidly rise in the scale of civilization. The inhabitants may be divided into three different classes, viz., the Malays, the Chinese, and the Dyaks; of the two former little need be said, as they are so well known. The Malays are not numerous, and, generally speaking, with the exception of the Borneo pan-gerans, are well inclined to aid me as far as lies in their power. The Chinese are about four hundred in number, and the only impediment to their immigrating is their poverty, and the present high price of provisions. The Chinese are industrious, but greedy, supple, and oppressive; they are divided into kunsis or companies, and a rival company to the one at present at Sarawak offers to bring three thousand men in a few months, provided they can get permission to do so. The Dyaks, by far the most interesting portion of the inhabitants, are confined almost entirely to the mountainous country, where they have fastnesses to which they fly on the slightest alarm. These people are mild, industrious, and so scrupulously honest, that a single case of theft has not come under my observation, even when surrounded by objects easily appropriated, and tempting from their novelty. In their domestic lives they are amiable, and addicted to none of the glaring vices of a wild state; they marry but one wife, and their women are always quoted amongst the Malays as remarkable for chastity, nor are they degraded as in many communities.

"The head-hunting, or taking the heads of their enemies, is a feature by no means new or extraordinary, and like the scalping of

Bornou.

Borneo.

the North American Indian, is a trophy of victory and prowess. Amongst the hill Dyaks this custom is confined entirely to the heads of enemies, and is the effect, not the cause of war; their wars are by no means bloody, and are never carried on but by small companies, who enter on the enemies' ground, and lie in ambush for parties or individuals of their foes. The exaggerated accounts of some travellers have been drawn from the more savage and predatory tribes of the coast; but these tribes have forsaken their original customs, and have joined piracy to their former practice of taking heads, and they are not different from other pirates who destroy as well as plunder.

"The hill Dyaks, such as I have briefly described them, are a most interesting race, and present more facilities for the amelioration of their condition than any other people. In general, however, they are sunk in misery, and too frequently exposed to famine; but, when only moderately oppressed, I have seen tribes who brought to mind the simplicity, if not the happiness, of primitive society. The number of these people in the country of Sarawak may generally be stated at ten thousand, but, with the slightest protection, numbers who have retired beyond the reach of their cruel oppressors, would return to their former habitations. Their freedom from all prejudice, and their scanty knowledge of religion, would render their conversion to Christianity an easy task, provided they are rescued from their present suffering and degraded state; but, until this be done, it will be vain to preach a faith to them the first precepts of which are daily violated on their own persons. Never, indeed, were people more oppressed, or more wretched; those who are far removed from witnessing their suffering and their patience may consider my sympathy and enthusiasm exag-gerated, but I cannot help expressing it. The Dyaks are always considered an inferior race, and a heavy penalty is imposed on them for committing any offence against a Malay; to kill a Malay under any circumstances of aggression, would subject them to death, or even worse punishment; to strike or scuffle with a Mahometan, though he be caught in the act of stealing their property, would likewise be a grave offence; even an accidental injury by a Dyak could only be explated by the confiscation of all, or nearly all, his property to the Malay. On the other hand, a Malay killing a Dyak is rarely punished, even by the imposition of a small fine, and the only inconvenience he suffers is being unable to visit that particular tribe, from a just fear of retaliation. The direct tax paid by the Dyaks to their local rulers is trifling in amount, but they suffer afterwards from all sorts of exactions, carried on by means of the most flagrant artifice or violence, by which they are often reduced to famine and starvation."

Sir James Brooke, in his generous and romantic enterprize, has had to contend with obstacles of appalling magnitude,—the barbarism of the inhabitants; chiefs whose power was exercised in cruel oppression and extortion over the down-trodden natives; rajahs who dreaded his power and influence; the jealousy of the neighbouring Dutch settlement; the envy of unsuccessful traders; and, above all, the dreadful scourge of extensive piracy. Nothing but an in-domitable courage, and an earnest zeal for the welfare and prosperity of the people and government intrusted to his care, could have sustained him, and carried him forward in his successful career. But in such a contest it was not to be expected that his enemies would refrain from attempts, open or concealed, to counteract his benevolent exertions if they interfered with their selfish designs. Attacks were made upon him in the Straits Times newspaper, and repeated in England, charging him with cruelties perpetrated on the natives; and, on the 10th of July 1851, a motion was brought forward in the House of Commons for a commission of inquiry into the proceedings of Sir James Brooke on the coast of Borneo, which was followed by an elaborate debate. The motion was rejected, and the conduct of Sir James virtually approved by a majority of 230 to 19. These attacks were renewed in the summer of 1853, when the government was persuaded to issue instructions to the governor-general of India, directing him to issue a commission to inquire how far the position which Sir James Brooke holds in Sarawak is advantageous to the commercial interests of Great Britain.

In the island of Labuan, next to the monster evil of piracy which scourges the Eastern Archipelago, one of the greatest difficulties the colony has to contend with is the panic which

arose in consequence of the sickness which prevailed in the Bornholm first year of the settlement. The improved sanitary condition of the island by the removal of a portion of the jungle, and a partial drainage in the vicinity of the habitations, has abated this apprehension, and the climate of Labuan, as compared with other tropical countries, may be considered as salubrious as any other. The population in 1851 was 1385. Of these 800 were a migratory population of Malay labourers: the fixed population was 585. Of these the deaths were 29, being 42 of the mortality of the year. This per-centage is unduly increased by including the Chinese, who, from their gross and dissipated habits, always exhibit a large mortality.

The island possesses considerable coal-fields, which are worked by the Eastern Archipelago Company, but in a way so unscientific—that is, by only quarrying the outcrops—as to prove both dilatory and expensive. In 1851 they exported 5032 tons. The examination that has been made of these coal measures has established their extent and value to be fully equal to the expectation formed of them. The large seam alone cannot contain less than 700,000 tons lying above tide-level.

The local revenue of 1850 only amounted to L.1798, and the total expenditure to L.4140. No public work of any great extent has been carried on; the chief outlay has been made in cutting down the forest, and making drains on the plain and near the site of the town, with the view of improving the sanitary condition of the island. (Leyden's Description of Borneo, in the Asiatic Journal; Hamilton's Gazetteer; Milburn's Oriental Commerce; Temminck's $L'Inde\ Archipèlagique$; $\ Letters\ of\ Sir\ James\ Brooke,\ by$ J. C. Templer; and Reports on the State of H.M. Colonies.)

BORNHOLM, an island in the Baltic, belonging to Denmark, in the Stift of Seeland, between Lat. 54. 59. and 55.18. N. and Long. 14. 42. and 15. 8. E. It is about 20 miles in length, by 14 in breadth, with a generally mountainous surface, and steep and rocky shores. It yields a good freestone, which is largely exported for building; and also limestone, blue marble, coal, and clay. The principal products of the soil are oats, flax, and hemp. The population amounts to about 26,000, chiefly engaged in agriculture, fishing, brewing, distilling, and the manufacture of earthenwares. The capital is Roenne.

BORNOU, an extensive kingdom, situated in Central With the exception of Houssa, now subject to the sultan of the Fellatahs, it is superior in power and influence to any other state in that quarter of the continent. Major Denham, to whom we are indebted for the first full and authentic description of this country, places it between the 12th and 18th degrees of east longitude, and the 10th and 15th of north latitude, which would form an extent of nearly 400 miles in every direction. His own map and description, however, oblige us to restrict these dimensions to little more than one-half. Bornou is bounded on the west by Soudan or Houssa, on the east by the Lake Tchad (or Tsad), on the north by the Great Desert, on the south by the kingdoms of Baghermi (or Begherme), Loggun, and Mandara.

According to the more recent information derived from the expedition under Richardson, Barth, and Overweg, the limits of Bornou have materially changed since the time of Major Denham, by having extended to the west as far as 9. 30. E. Long. The grandest natural feature of this country is Ladre Tchad, an extensive inland water, at least 120 miles in length and 60 miles in breadth. remarkable variation, however, takes place, according as the rivers by which it is fed are swelled by the tropical rains, or their channels reduced by the continuance of the dry season. At this period the waters on every side recede, and leave uncovered a tract of many miles in extent, to be again overflowed when the rains have swelled the The inhabitants, however, derive little advantage from the short and precarious interval during which they

Bornou. have access to this portion of their territory. There is are now unacquainted. D'Anville, however, proceeding Bornou. neither leisure nor opportunity to bring it under regular culture; and the luxuriant fertility derived from the he could not find a positive authority, expunged these inundation is wasted in producing a rank vegetable growth of grass from ten to twelve feet in height, with impenetrable thickets of trees and underwood. Man scarcely dares to penetrate into these gloomy regions, which are filled by numerous and formidable wild animals, elephants, lions, hyenas, and enormous broods of the serpent species. These creatures, when the inundation comes on, seek refuge in the cultivated and inhabited tracts, where their arrival diffuses consternation and dismay.

The rivers by which this great expanse of water is fed are the Yeou and the Shary. The former, which enters it from the west, excited great interest on its first discovery, from being considered, or at least suspected, to be a continuation of the Niger of Park. Further observation has completely disproved this supposition, and shown it to be a river of only secondary magnitude. Rising in a range of hills to the south of Houssa, it flows first north, then eastward through Bornou, till it falls into the Tchad; but it never, unless when swollen by the rains, presents any great body of water. The Shary is a much more considerable river. It rises in the far unknown interior to the south. Dr Barth crossed it on his journey to Baghermi, and traced its course by native informations as far south as 8. 30. N. Lat. At Kusseri, not far from Lake Tchad, it received a large tributary, the River Loggene, which was mistaken by Denham for the Shary itself.

The territory of Bornou, extending along the whole western and part of the southern and northern shores of the great lake, is generally level and fertile. The climate, especially from March to the end of June, is oppressively hot, rising sometimes to 105 and 107, and even during most of the night not falling much below 100. In May the wet season commences, with violent storms of thunder and lightning. In the end of June the rivers and lakes begin to overflow, and for several months the rains are almost incessant, accompanied with damp, cloudy, and sultry weather. The inhabitants at this season are severely afflicted with fever and ague, which carry off great numbers of them. In October the rains abate; cool, fresh winds blow from the west and north-west; and for several months the climate is both healthful and agreeable.

No mention is found of Bornou among the geographers of antiquity, although it may be conjectured that the great lake of Nigritia, placed by Ptolemy in the centre of Africa, was perhaps the Tchad. Edrisi, however, in the twelfth century, describes this country under the appellation of Kuku, which is still borne by its capital. He represents the king as absolute and powerful, with a numerous army and the merchants as carrying on an active trade and possessing great wealth. Leo, who visited it about two centuries after, gives a description nearly similar. The people are represented as Pagans, and extremely rude, though numerous, and the country well cultivated. The merchants from Barbary supplied the king in his expeditions with arms and horses, while he made an annual expedition to procure slaves to be given in payment.

No further relations respecting Bornou were communicated to Europe during a very long period; yet it is remarkable that, in the maps of Sanson, Delisle, and others of the sixteenth and seventeenth centuries, there is found a lake of Bornou, and in some of them a large lake with the name of Guardia, which does not sound very dissimilar to that of Tchad. It is difficult to conjecture the ground upon which these features were delineated; yet their coincidence with those recently discovered seems to show that they were founded upon some information with which we

upon his rigid principle of admitting no object for which names from his map, and has been generally followed by modern geographers.

When the African Association in 1788 commenced their operations, they early received some information, collected by Mr Lucas at Tripoli, with other particulars related by Ben Ali, a Moorish merchant resident in London. From these sources were derived pretty copious notices, both concerning Bornou and Cassina; the former being described as what it then appears to have been, decidedly the ruling power in the interior of Eastern Africa, all the kingdoms of which it had reduced into a state of vassalage. In arranging these accounts, however, a considerable error was committed as to the position of this country. Mr Lucas had been informed that it was fifty journeys, or about six hundred and fifty miles, south from Fezzan; but his informant added that it was only twenty-five journeys west from the Nile. To meet this statement Major Rennell conceived it necessary to extend the route, not due south as it really was, but south-east, so as to place it in the heart of the desert, seven degrees north and eight degrees east of its real position. Kuku, likewise believed, from the statement of Edrisi, to be a separate kingdom, was placed in the same quarter, still nearer to the Nile; and thus the desert tract to the west of Nubia was filled with

countries which, in that quarter, have no existence. The expedition sent out by the British government in 1822, under Denham and Clapperton, completely adjusted the geography of this part of the continent. It was discovered that Bornou, instead of being so far removed, as our maps represented, from Houssa and Cassina, was close on their eastern frontier, and formed a continuation of that extensive, fruitful, and finely watered plain, which extends from the mouth of the Senegal across Central Africa. Its relative political circumstances had also undergone, during this interval, a very complete change. Instead of holding all the surrounding states in vassalage, it had been itself completely subjected to the dominion of the Fellatahs, who, after subjugating all Houssa, had invaded Bornou, and committed the most dreadful ravages, destroying its capital and other large cities, and bringing the whole country into a state of entire bondage. There was still, however, among the people a strong spirit of valour and independence. A mere private individual, in the northern province of Kanem, pretending to, and perhaps himself trusting in, a celestial mission, hoisted the green flag of the Prophet, and, under the title of the servant of God, undertook a series of struggles for the deliverance of his country. The Fellatahs appear to have and many attendants; the people as martial, though rude; been taken very much by surprise, and, being defeated in successive encounters, were in ten months driven completely out of Bornou. They seem to have now given up all attempts at reconquering it, although a hostile spirit still reigns between the two countries.

The conqueror, called, from his native province, El Kanemy, having the army wholly devoted to him, might probably have with little difficulty assumed the sovereign More moderate, and perhaps more prudent, he drew forth the nearest heir of the ancient sultans, and invested him with all the appearance and pomp of sovereignty; reserving only for himself, under the title of scheik, all its reality. The court of the sultan was established at New Bornou, which was made the capital, instead of the old city, which had been entirely destroyed during the Fellatah invasion; while the scheik, in military state, resides at the city of Kuku or Kouka.

The Bornouese throne in former times had been elective, at least among the members of the same family; and at present the scheik possesses a power nearly absolute, which he exercises with salutary vigour. Bands of robbers who desolated the country have been nearly extirpated, and travelling and property rendered secure, at least in the interior. Justice within each city is administered, as in other Mussulman countries, by the cadi, with an appeal to the scheik. Murder is punished, on conviction, by delivering the offender to the relatives of the deceased, who dispatch him with clubs. A young thief is buried in the ground up to the head, which being covered with butter and honey, is exposed under the burning sun to the attack of innumerable flies and mosquitoes. scheik's zeal was peculiarly directed against moral offences, of which conscience and public opinion have been generally considered as the most appropriate guardians. Such were the non-observance of the Mahommedan fasts, upon which severe and relentless penalties were levied. He was also most strict in punishing those failings in the female sex which are elsewhere considered as sufficiently visited by disgrace and exclusion from society. Here not only the most ignominious punishments, but often death itself, awaited them. On one occasion sixty of these unfortunate offenders were brought before him, of whom five were hanged, and four whipt so severely that two afterwards expired; an outrageous virtue, which seems with reason to have been branded as almost diabolical. The most frivolous female offences, as talking too loud, and walking in the street with the face unveiled, were considered as ground of public indictment at this severe bar. Even the spending in courtship or otherwise a larger sum than a man was supposed to be able to afford, gave ground for dragging him before the national tribunal. Denham saw one thrown into prison for presenting to his bride two robes or turkadoes, when his station was considered as not authorizing more than one; although he proved that the lady had refused her consent on any other terms; which, however, drew upon her also a severe animadversion.

The sultan of Bornou is surrounded by a mounted body-guard, who likewise compose his principal nobles and chiefs. Their attire and equipment is the most grotesque and unwieldy, perhaps, to which fashion in any country has given rise. It is indispensable to the chief of rank that he should possess a huge belly, the singular importance attached to which is probably founded on the idea of its being an indication of plenty and luxury; and it is held so essential, that even when high feeding cannot produce the effect, stuffing is employed to give the appearance of it. Again, even in this burning climate, the body is enveloped in successive robes, amounting often to ten or twelve, the number being always considered as indicating the rank of the wearer. The head likewise is inclosed in numerous successive turbans, which are supposed to be rendered more ornamental by leaving only one side of the face uncovered. The sultan studies to be still more protuberant and more loaded with clothing than any of his courtiers. Yet in this attire he and they advance together into the field; but of course they can have no real efficiency in the duties of active warfare. The last sultan had fallen in consequence of the impossibility, caused by his ponderous equipment, of flying with sufficient speed before a victorious enemy.

The military force of Bornou consists almost entirely in cavalry, amounting to about 30,000, who are mounted on small but active steeds, which, as well as their riders, being cased in iron mail, present a very formidable appearance. They also manage their horses with the ut-

Bornou, the nobles possessed this and other high privileges: but rapidly and dexterously. Their only defect is, that when Bornou. placed in the field against an enemy at all formidable, they can by no impulse be induced to fight. They look on as spectators till the contest issues in victory, when they engage eagerly in pursuit and plunder, in both of which they excel; whilst, in case of defeat, they take to flight with the utmost rapidity. As, however, the cavalry of the armies with which they contend are nearly on a level in point of prowess with themselves, the match is tolerably equal. There are usually on each side about a hundred chiefs, raised to distinction by bodily strength and prowess, who engage in single combats, and display often the most desperate valour. Barca Gana, the scheik's general, Insolvent debtors are rather hardly dealt with. But the had obtained the reputation of possessing charms that rendered him invulnerable. The main dependence of that prince is upon a body of 9000 spearmen from his native territory of Kanem, who rally round him with the most enthusiastic attachment. Though almost naked, and equipped only with shield and spear, they display a discipline beyond that of almost any other African army. They march by tribes, and keep in front of their line a regular chain of piquets, with sentinels, who every half hour pass the war-cry along it; precautions very rarely employed in barbarian armies. All the sovereigns of Central Africa likewise consider themselves fortunate if they can engage the services of even a small party of Arab caravan followers, who, being brave and armed with muskets, an instrument yet almost unknown in this region, are objects of something like supernatural dread.

> The territory of Bornou is fertile and well watered, yielding large crops even under very imperfect cultivation. The labour is chiefly performed by female slaves, who, at the commencement of the rainy season, scratch rather than turn the ground, and scatter rather than sow the seed. They are also obliged to watch the growth, in order to guard against numerous animal depredators; a very perilous occupation, in the course of which they are liable to be carried off by the wild beasts, who are roaming about in every direction. The rice and wheat are inferior, and grown in small quantity. The grain which forms the staple food of the people is a species of millet called gussub, which they form, not into bread, an article here entirely unknown, but into a species of paste, that, by the addition of butter and honey, forms the highest boast of Bornou cookery. Cotton and indigo are also valuable productions, affording the material for the cloths finely dyed with blue stripes, which form the staple fabric of the country. All the domestic animals are reared, and very numerous herds of oxen are possessed, chiefly by an Arab tribe called Shouaas. Major Denham reckons 20,000 on the shores of the Tchad, and double that number on the banks of the Shary. The empire, however, is remarkably destitute of the products of horticulture. There is neither a fruit nor a vegetable, except some onions in the vicinity of the large towns, and a very few limes and figs reared with great difficulty in the garden of the scheik.

The wild animals are very numerous, finding both food and cover in the extensive woody and marshy districts. Lions prowl about in considerable numbers, approaching even the walls of the towns. The Bornouese delight in taming and even making a pet of this noble animal. The scheik, as a special favour, sent Major Denham a present of a young lion, which he very prudently returned, lamenting the want of space for his accommodation. Elephants, in herds of fifty to four hundred, wander over the tract inundated by the Tchad, and are hunted and killed both for the flesh and the ivory. Hyenas also, in huge and formidable bands, invade the cultivated most skill, and perform all the manœuvres of the field most fields, and are with difficulty prevented from penetrating

Bornou. into the towns. The tall form of the giraffe is not un- and a complexion of light copper; and they exhibit a Bornou. - frequently seen cropping the leaves of the dense forest. strong though improved resemblance to the European The waters abound with crocodiles and hippopotami, and the flesh of both is valued for food; that of the former, indeed, is described by naturalists as extremely delicate. The country is filled with swarms of bees, which often obstruct the passage of the traveller; and the honey, though only partially collected, forms one of the chief Bornouese delicacies. Antelopes, gazelles, ostriches, and admission into the houses, they not only sell these gifts various other quadrupeds and feathered animals, are pursued as game.

The population of Bornou is calculated by Major Denham at 5,000,000; but by Dr Barth, basing his estimate on the experience and explorations of three years, at no less than from 8,000,000 to 9,000,000. The leading people, called Bornouese or Kanowry, present a complete specimen of the negro form and features; having large mouths, thick lips, broad noses, an unmeaning face, but good teeth and high foreheads. The females heighten their want of beauty by a most extensive and injudicious system of puncturing and tattooing. The people are peaceably disposed, friendly and courteous in their manners, and distinguished by a sort of good-natured heaviness. Though endowed with a slender degree of courage, they are resentful, and addicted to petty larcenies. law allows of polygamy, but the richest have seldom more than two or three wives, and the rest of the community The favourite amusement is wrestling, not performed in person, but viewed as a spectacle while performed by slaves taken in war from the neighbouring nations, particularly the Beghermes and Musgows. The displays of strength made by these men are said to be often very extraordinary. A powerful wrestler sells at a high price, and the masters place extraordinary pride in the performance of their slaves, cheering them during the combat, and, on its successful issue, often presenting them with valuable robes. Even the ladies of Bornou engage occasionally in public contests, where they often throw each other with violence to the ground. Another favourite amusement consists in a rude game bearing some resemblance to chess, played with beans and holes in the sand.

The Mahommedan religion is universally professed in Bornou, and even with violence and bigotry. Through recommendations brought with them, the English travellers secured good treatment; but, as unbelievers, they were viewed with the deepest horror, and almost as a species of monsters. Even from those who showed at first the most friendly disposition, the disclosure of their creed drew forth deep groans, sometimes screams, and usually arrested all progress to intimacy. A man who had served them for two or three weeks, although he pleaded that it was only under the most extreme necessity, was declared unfit on that ground to be received as a witness in a number of fighis (writers or doctors), who have visited Mecca, and are well skilled in Arabic. It is even an employment to write copies of the Koran, which are sent into Barbary, where they bear a considerable price. Its verses are much used as charms or amulets, in the préparation of which the scheik was understood greatly to excel, gaining almost as many victories by his pen as by his sword. The Bornouese, like other negroes, have songs relating to love or war, some of which are said to possess merit; but their intellectual character in general seems to rank extremely low.

tribe called Shouaas, who are accounted Arabs, and speak must not be forgotten that the route from that city, that language, though they have scarcely any resemblance though the nearest of any from the coast, greatly exceeds to those in the north bearing that appellation. They have a thousand miles, through the most dreary and desolate tine open countenances, with aquiline noses, large eyes, tracts, amid the domains of numerous predatory tribes.

gipsies. Their deportment, however, is not very favourably spoken of. They do not want courage, and can furnish the government when necessary with 15,000 horse; but they are arrogant and deceitful, imposing upon the people by the manufacture of charms, and by pretensions to prophecy and fortune-telling. Having thus gained at a high rate, but embrace opportunities of pilfering. Probably they were observed to disadvantage in the heart of the cities. One of their tribes, called Dugganahs, who were visited in their native tents on the Shary, presented a most pleasing picture of patriarchal simplicity. Their countenances were noble and expressive, and the attachments of kindred and domestic affection were displayed in peculiar force. Another tribe, called the La Salas, almost independent of Bornou, inhabit a number of low islands in the Tchad, covered with rich pasture, and separated from the continent by channels so shallow as to be fordable on horseback. A knowledge of the tracts is however requisite; and those troops who without it attempted to penetrate through them have got entangled in mud, sunk into

deep pools, and signally defeated.

The towns in Bornou are of considerable size, surrounded with walls thirty-five or forty feet in height, and twenty feet in thickness, having at each of the four corners a triple gate, composed of strong planks of wood, with bars of iron. The abodes of the principal inhabitants form an inclosed square, in which are separate houses for each of the wives; whilst the chief himself resides in two or more elevated structures resembling turrets, connected together by terraces. These are well built, of a reddish clay, highly polished, so as to resemble stucco; whilst the interior roof, though composed only of branches, is tastefully construct-The horns of the antelope and gazelle are employed to fasten together the different parts, and have suspended from them the quiver, spear, and shield of the owner. The ordinary houses are small, being built partly of mud and thatched, partly only of straw or coarse grass mats. Major Denham was accommodated in one of eight feet diameter, having a hole two and a half feet high, by which he crept in and out; but this deficiency of aperture was rendered almost necessary by the crowds of tormenting insects who would otherwise have made good their entrance. Though New Bornou and Kouka were the residences, the one of the sultan and the other of the scheik, neither is equal in magnitude to Angornou, estimated to contain 30,000 inhabitants, who, on market days, are swelled to 80,000 or 100,000. On the Yeou are seen the ruins of Old Bornou and Gambarou, which appear to have been greater and better built cities than any now in the kingdom; but they had been so entirely destroyed by the Fellatahs in their court of law. There are resident in Bornou a considerable late invasion, that the very site is in a great measure covered with shrubs and vegetation. The vicinity is almost laid waste by the inroads of the Tuaricks; and, indeed, all the kingdoms of Central Africa suffer the disadvantage of having their frontier exposed to the ravages of predatory tribes who occupy the rude and desert borders.

The English travellers have held out favourable hopes of the commerce which might be opened with Bornou. They observed the increased and increasing demand, among a numerous population, for goods which Britain either does or could produce cheaper than any other country; and these goods were found selling at an advance of 300 per The pastoral districts of this country are occupied by a cent. above their price at Tripoli. On the other hand, it Borough.

Borodino The merchant has to encounter, therefore, not only accumulated hardships, but all the perils of famine, battle, and pestilence. It would be vain, therefore, to expect that any one would conduct such a trade without very high It is at present carried on by merchants, or rather chiefs, each with a large body of armed followers, alike prepared for commerce or war. The European who should engage in such a trade would be obliged to follow this example, and might expect to encounter their enmity and rivalry. It seems doubtful, therefore, how far such a trade could now be carried on by any other than its present channel.

Amongst the commodities which find a market in Bornou are mentioned writing paper, beads, coral, silks and cottons of gaudy patterns, turbans, small carpets, brushes, caftans, and shirts ready made; brass basins tinned, small mirrors, pistols, and other arms ornamented, but cheap. The commodities taken in return are almost exclusively slaves, obtained by purchase or capture; and we fear it will be more difficult than Major Denham supposed to divert the trade from this bad channel. Neither gold nor silver are seemingly to be procured in Bornou. Elephants' teeth, ostrich feathers, raw hides, musk, indigo, and senna, are mentioned as commodities suited to the market of

BORODINO, a village in Russia, near the river Moskwa, about ninety miles west of Moscow; remarkable for the terrible battle fought there on the 7th of September 1812, between the French and Russians, in which the latter were defeated.

BORON. See CHEMISTRY.

BOROUGH, BURROUGH, Borow, or Burgh (Saxon beorg), is a term frequently used for a town or corporation which is not a city. A borough is by some supposed to have primarily meant a tithing or company consisting of ten families, who were bound and combined together as sureties for one another. Afterwards, as Verstegan informs us, borough came to signify a town that had something of a wall or inclosure about it: so that all places which amongst our ancestors had the denomination of borough, were one way or other fenced or fortified. But in latter times this appellation was also bestowed on several of the villæ insigniores, or country towns of more than ordinary note, though not walled. The ancient Saxons, according to Spelman, gave the name of burghs to what in other countries were called cities. But different canons being made for removing the episcopal sees from villages and small towns to the chief cities, the term city came to be attributed to episcopal towns, whilst that of borough included all the rest, even although they had the appearance of cities, as being governed by mayors, having bye-laws of their own making, sending representatives to parliament, and being fortified with a wall and castle, and the like.

Royal Boroughs or Burghs, in Scotland, are corporations originally created for the advantage of trade, in virtue of charters granted by several of the kings, and having the privilege of sending commissioners to represent them in parliament, besides other peculiar privileges. royal burghs are not only so many distinct corporations, but also constitute one entire body, governed by, and accountable to, a general court, anciently called the court of four boroughs, which was held yearly, to treat and determine concerning matters relating to the common interest. The four burghs which composed this court were, Edinburgh, Stirling, Roxburgh, and Berwick; but the last two falling into the hands of the English, Linlithgow and Lanark were substituted in their room, with a saving to the former whenever they should return to their allegiance. But this court not being sufficient to answer the necessities of the royal burghs, they were all empowered under James III., in 1487, to send commissioners to a yearly convention of their own,

which was then appointed to be held at Inverkeithing, but Borough is now held at Edinburgh, under the denomination of the Convention of Royal Burghs, which was vested with great Borromean powers, and had for its object the benefit of trade, and the Islands. interest of the burghs generally. See MUNICIPAL CORPO-RATIONS.

Borough-English, a customary descent of lands or tenements, in some ancient boroughs and copyhold manors, by which the youngest son, and not the eldest, succeeded to the burgage tenement on the death of his father.

Boroughs, Representation of. See Parliament.

BOROUGHBRIDGE, a borough and market town of England, in the west riding of Yorkshire, wapentake of Claro, and parish of Aldborough. It is situated on the south bank of the river Ure, which is navigable here, and is crossed by a stone bridge seventeen miles N.W. of York. It is chiefly indebted for its importance to its situation on the great road from York to Edinburgh; and, previous to the passing of the Reform Act, it returned two members to parliament. Many British and Roman antiquities have been found in the town and vicinity, of which the most celebrated are the three obelisks called "The Arrows," about half a mile south of the town. Several fairs are annually held here. Pop. (1851) 1095.

BOROVSK, a town of European Russia, capital of a circle of the same name in the government of Kalouga. It is situated on the Prorva, 55 miles S.W. of Moscow. Pop. 5000. It has considerable manufactures of sailcloth, and in the vicinity is a rich convent, founded in 1444.

BORRELISTS, a sect of Christians in Holland, so called from Borrel, their founder. They reject the use of the sacraments, public prayer, and all external acts of worship.

BORRICHIUS, or Boron, Olaus, one of the most learned men of his age, was born in 1626, at Borchen in Denmark. He studied medicine at Copenhagen, and began to practise during a terrible plague which ravaged that city. He was appointed professor of botany and chemistry; and in 1660 he visited Holland, England, and France; was received as doctor at Angers; and visited Rome in 1665. In the course of his travels he attended the most celebrated schools, and was selected by Queen Christina as her master in chemistry. He returned to Copenhagen in 1666, and discharged the duties of his office with great assiduity, as his works abundantly testify. He was made a member of the supreme council of justice in 1686, and counsellor of the royal chancery in 1689. He died of the operation of lithotomy in 1690.

The following are the principal works of Borrichius:—1. Dokimasia Metallica, Copenhagen, 1660, 8vo; 2. De Ortu et Progressu Chemico Dissertatio, ibid. 1668, 4to; 3. Hermetis, Ægyptiorum, et Chemicorum Sapientia, ibid. 1674, 4to; 4. Lingua Pharmacopæorum, ibid. 1670, 4to; 5. Cogitationes de variis Linguæ Ætatibus, ibid. 1675, 8vo; 6. De Causis diversitatis Linguarum, ibid. 1675, 4to; 7. De Somno et Somniferis, Francfort, 1680, 1683, 4to; 8. De Usu Plantarum Indigenarum in Medicina, Copenhagen, 1688, 1690, 8vo; 9. Dissertationes V. de Poetis Græcis et Latinis, ibid. 1676; 10. Conspectus Chemicorum Scriptorum Illustriorum, ibid. 1696, 4to; 11. De Antiqua Urbis Romæ Facie, ibid. 1697, 8vo; 12. De Urbis Romæ Primordiis, ibid. 1687, 4to; &c., &c.

BORROMEAN ISLANDS, a group of four small islands on the western side of Lago Maggiore, in Continental Sardinia. Up to the middle of the seventeenth century these islands were mere barren rocks. About this time Vitaliano, Count Borromeo, master-general of the ordnance to the king of Spain, directed that they should be covered with earth from the neighbouring banks of the lake; and, at an enormous expense, the islands were converted into pleasure gardens. The most celebrated of these are the Isola Bella, and the Isola Madre. The others are called the Isola S. Giovanni or Isolino, and the Isola Superiore or de' Piscatori, which contains a small fishing village of about four hundred inhabitants, with a parish church. Isola Bella

Borromeo. appears in ten successive terraces, rising one hundred and thirty feet above the level of the water, each regularly decreasing in size from the base to the summit, which is an oblong surface, seventy feet by forty in extent, paved and surrounded by a balustrade. The whole are environed by gigantic marble statues of gods, goddesses, and horses, or other figures; and the walls are clothed with the finest fruittrees and evergreens, many of which belong to the southern climates. There is, besides, a magnificent palace towards the western end of the island, close to the lake, which almost washes its walls. It is built on arches, which are formed into grottos, with a floor of mosaic, representing various objects, and decorated also with shell-work and marble. The palace itself contains a profusion of marbles and paintings; and some flower-pieces executed on marble, have been particularly admired, as also busts and statues. At the angles of the garden, which has a southern exposure, there are two round towers with lofty chambers adorned with red and white marble; and in the vicinity are groves of laurels, orange-trees, lofty cypresses, and other odoriferous plants, rendering it a delightful retreat. Isola Madre, which is the largest of the islands, is between one and two miles from Isola Bella; it consists of a superstructure of seven terraces, apparently lower, but not less beautiful, than the other. It is, however, of equal height in reality, the base being a perpendicular rock, rising considerably out of the water, and on that account not requiring so much covering. Here also there is a palace embellished with paintings and different ornaments; and in the gardens are groves of citrons, cedar, and orange-trees, besides a summer-house close to the lake. All the decorations are necessarily on a limited scale; and it excites the wonder of the spectator, that in a space so small so much has been done. When any foreign prince visited these islands in the night, or resided upon them, they were illuminated with various coloured lights. The expense of keeping them in the same state since 1671, about which time they seem to have been finished, has of course been very great. They are fre-" If anything," quently called the "Enchanted Islands." says Coxe, speaking of the Isola Bella, "justly gives this island the appellation of enchanted, it is the prospect from the terrace. The gradual diminution of the mountains, from the regions of eternal snow to the rich plain; the sinuosity of the lake; its varied banks; the bay of Marzozzo, bounded by vast hills; the neighbouring borough of Palanza, and more distant view of Laveno, the numerous villages, the Isola Madre, and another island sprinkled with fishermen's huts, form a delightful assemblage."

BORROMEO, CARLO, a Romish saint, was the son of Ghiberto Borromeo, Count of Arona, and of Mary of Medicis, and was born at the castle of Arona, upon the Lago Maggiore, in the Milanese, Oct. 2. 1538. When he was about twelve years old, Julius Cæsar Borromeo resigned to him an abbacy, the revenue of which he applied wholly in charity to the poor. He studied the civil and canon law at Pavia under the learned Francis Alciat. In 1554 his father died; and, although he had an elder brother, Count Frederick, he was requested by the family to take the management of their domestic affairs. After a time, however, he resumed his studies, and in 1559 he took his doctor's degree. In the following year his uncle Cardinal de' Medicis was raised to the pontificate, by the name of Pius IV.; and Borromeo was made prothonotary, intrusted with both the public and privy seal of the ecclesiastical state, created cardinal deacon, and soon after archbishop of Milan. In compliance with the pope's desire, he lived in great splendour; yet his own temperance and humility were never brought into question. He established an academy of select and learned persons, each of whom was to write on some chosen subject, either in verse or in prose, and to communicate to the society the fruits of his studies. The works thus produced were pub-

lished in several volumes at Venice in 1748, under the title Borromeo. of Noctes Vaticana. About this time he also founded and endowed a college at Pavia, which he dedicated to Justina, virgin and martyr.

Upon the death of his elder brother Frederick, his friends, and even the pope himself, advised him to quit the church, and marry, that his family might not become extinct. Contrary to expectation, however, he declined the proposal; and from that time became more fervent than ever in the exercises of piety, and more zealous for the advancement

of ecclesiastical knowledge.

On the death of Pius IV., January 7. 1566, the skill and diligence of Borromeo materially contributed to stifle the cabals of the conclave. As soon as tranquillity had been re-established, Borromeo devoted himself wholly to the reformation of his large and important diocese, where the most flagitious irregularities were openly practised. He began by making pastoral visits in his metropolis; and by a variety of wise and necessary regulations, he soon restored proper decency and dignity to divine service. In conformity to the decrees of the council of Trent, he cleared the cathedral of its gorgeous tombs, rich ornaments, banners, arms, &c., sparing not the monuments even of his own relations. Nor did his zeal stop here. He divided the nave of the church throughout its whole length into two compartments, so that the sexes, being separated, might perform their devotions with feelings suitable to the place. He proceeded next to the collegiate churches, and even to the fraternities of penitents, particularly that of St John the Baptist. The reformation of the monasteries followed that of the churches; and the vigilance of the archbishop soon extended itself from the city to the country round it. The great abuses which had overrun the church at this time arose principally from the ignorance of the clergy. In order, therefore, to attack the evil at its root, Borromeo established seminaries, colleges, and communities, for the education of young persons intended for holy orders. He met with much opposition in his endeavours to bring about a reformation of manners; but by an inflexible constancy, tempered with great sweetness of manners, he prevailed against every obstacle, and succeeded in rendering the most important services to the cause of morals as well as religion. The governor of the province, and many of the senators, apprehensive that the cardinal's ordinances and proceedings would incroach upon the civil jurisdiction, addressed many remonstrances and complaints to the courts of Rome and Madrid. These, however, in as far as concerned the king of Spain, Philip II., were referred entirely to the decision of the pope. But Borromeo had more formidable difficulties to struggle with, in the inveterate opposition of several religious orders, particularly that of the Brothers of Humility. Three provosts of the society entered into a conspiracy to cut him off; and one of their confederates, Jerome Donat, surnamed Farina, took upon him to carry the design into execution. For this purpose he mixed with the crowd in the archiepiscopal chapel, where Borromeo spent an hour every evening in prayer with his domestics and other pious persons; and having watched his opportunity, he fired at him with a heavily loaded arquebuss. The shot, strange to say, took no effect, though it was affirmed to have ruffled the rochet of the cardinal. His escape was believed to be miraculous, and was certainly wonderful, considering that the assassin had taken his station within five or six paces of his intended victim. At the moment when the shot was fired the choir were chanting the fine old melody, Non turbetur cor vestrum neque formidet; and it is said that the cardinal continued the service without any apparent emotion.

In the year 1576 the city and diocese of Milan were visited by the plague, which swept away great numbers. On this occasion Borromeo, with a spirit truly Christian and heroic, went about giving directions for accommodating the sick and Borseholder.

Borromeo burying the dead, avoiding no danger, and sparing no expense. Nor did he content himself with establishing proper regulations in the city, but went into all the neighbouring parishes where the contagion raged, distributing money, providing accommodation for the sick, and punishing those, especially the clergy, who were remiss in discharging the duties of their calling. Notwithstanding the fatigue and perplexity which he experienced in thus executing his pastoral charge, he abated nothing of the usual austerity of his life; bread and water constituting his humble daily fare.

But continual labours and austerities combined to shorten his valuable life. He was seized with an intermittent fever, and died at Milan, Nov. 4. 1584. He was immediately worshipped as a saint, but was not canonized till 1610. Besides the Noctes Vaticane, to which he appears to have contributed, the only literary relics of this intrepid and zealous reformer are some homilies, discourses, and sermons, with a collection of letters. Several lives of him have been published, viz., by Godeau; by Touron, a Dominican; by Ribadeneira, a Spanish Jesuit; and by Bimeus, and others. Through all the mist of absurdity and superstition in which the character and actions of Borromeo have been involved, it may safely be affirmed that if the Church of Rome had had many such men, religion might have been spared some grievous wounds, and Europe many afflicting and sanguinary convulsions.

Borromeo, Frederigo, nephew or cousin-german of the preceding, and likewise a cardinal and bishop of Milan, is chiefly known as the founder of the Ambrosian library. See LIBRARIES. He died A.D. 1632. He was the author of Meditamenta Litteraria (published in 1633, 4to), and

some other works.

BORROMINI, Francesco, an Italian architect, born at Bissone in 1599. He was much employed in the middle of the seventeenth century at Rome; but in his style he affected originality and richness, which corrupted the noble simplicity of the older schools, though his compositions are occasionally imposing. His principal works are the church of St Agnese in Piazza Navona, the church of San Carlo alle Fontane, the church of Collegio di Propaganda, and the restoration of San Giovanni in Laterano. He died by his own hand at Rome in 1667.

BORROWSTOWNNESS, by abbreviation Borness, one of the oldest seaport towns of Scotland, is in the county of Linlithgow, on the shore of the Firth of Forth, N. Lat. 56. 2. W. Long. 3.35. Though now decaying, it was formerly a place of considerable traffic, and had many ships engaged in colonial and foreign trade. Its commerce is now for the most part confined to the Baltic, but it still sends a few ships annually to the whaling. The harbour is excellent, but is now no longer able to defray current expenses, especially since Grangemouth began to rise into importance. In the town there are extensive manufactories of salt, of which 30,000 bushels are annually exported. A good many ships were formerly built here, and the patent slip is still frequently used. Besides the salt works, there are two distilleries, a pottery, rope-work, and vitriol and soap works. There are also valuable collieries in the neighbourhood, some of which have been worked for centuries, and extend under water to the distance of a mile. Besides the parish school, there are several private institutions. The most interesting objects in the parish are Graham's Dyke (a part of the Roman wall of Antonine), and Kinniel House, for many years the residence of Dugald Stewart. Pop. (1851) 2645.

BORSEHOLDER (borough's elder), among the Anglo-Saxons, one of the lowest magistrates, whose authority extended only over one free burgh, tithing, or decennary, consisting of ten families. Every freeman who wished to enjoy the protection of the laws, and not to be treated as a vagabond, was under the necessity of being admitted a member of the tithing where he and his family resided; and in order to obtain this admission, it was necessary for him to main-

tain a good reputation, because all the members of each tithing being pledges for one another, and the whole tithing sureties to the king for the good behavour of all its members, they were very cautious in admitting any into their society who were of bad or doubtful character. Each tithing formed a little state or commonwealth within itself, and chose one of its most respectable members for its head, who was sometimes called the alderman of such tithing or free burgh, on account of his age and experience, but most commonly borseholder, from the Saxon words borch, a security, and alder, a head or chief. This magistrate had authority to call together the members of his tithing, to preside in their meetings, and to put their sentences in execution. The members of each tithing, with their tithing-man or borseholder at their head, constituted a court of justice, in which all the little controversies arising within the tithing were determined. Any dispute of great difficulty or importance was referred to the next superior court, which was that of the hundred.

BORYSTHENES, in Ancient Geography, the largest river of Sarmatia Europæa, now called the Dnieper. Its sources were unknown to the ancients. (Herod. iv., Mela, ii.)

BOS. See MAMMALIA, Index.

Bos (βοῦς), a very ancient Attic silver coin or didrachmon: it was sometimes, though rarely, struck of gold. This coin was so called from having on it the impression of an ox; hence the phrase Bos in lingua, applied to one who had taken a bribe to hold his tongue.

BOSA, a city on the western coast of the island of Sardinia, in a fine valley on the northern bank of the Termo. It is well built and paved; is the see of a bishop; and has a cathedral, a diocesan seminary, and several schools. The harbour is safe, being sheltered by the islet of the same name. Pop. 6000. Long. 8. 25. 31. E. Lat. 40. 16. 40. N.

BOSCAGE, a grove or thicket. It is used in old laws for the food of cattle yielded by trees and bushes.

BOSCAN, Almogaver, Juan, a Spanish poet, born of a good family at Barcelona about A.D. 1500. He was the intimate friend of Garcilaso de la Vega, and with him contributed essentially to the improvement of Spanish poetry. He was the first who introduced hendecasyllabic verse into Spanish poetry; and he translated into the Castilian tongue the sonnets and other poetical forms consecrated by the usage of the best Italian authors. His poetry is divided into three books, the first of which contains only redondillas, while the two others are filled with the pieces which he composed after he adopted his new method, namely canciones, sonnets, tercetts, compositions in the ottava rima, and in blank verse. Boscan was tutor to the celebrated Ferdinand of Toledo, Duke of Alva, and appears to have died about the year 1544. His works were printed in conjunction with those of his friend Garcilaso, at Lisbon in 1543; at Leon

in 1549; and at Venice in 1553. (Bouterwek, i. 232.) BOSCAWEN, EDWARD, a brave British admiral, was the third son of Hugh Lord Viscount Falmouth. Having early entered into the navy, he was, in 1740, captain of the Shoreham; and he behaved with great intrepidity as a volunteer under Admiral Vernon, at the taking of Porto-Bello. At the siege of Carthagena, in March 1741, he had the command of a party of seamen who resolutely attacked and took a battery of fifteen 24-pounders, though exposed to the fire of another fort of five guns. In 1744, when in command of the Dreadnought of sixty guns, he captured the Medea, a French man-of-war commanded by M. de Hocquart, the first ship taken in that war. In May 1747 he signalized himself under the admirals Anson and Warren, in an engagement with the French fleet off Cape Finisterre, and was wounded in the shoulder with a musket-ball. Here M. de Hocquart, who then commanded the Diamond of fifty-six guns, again became his prisoner; and all the French ships of war, ten in number, were taken. On the 15th of July

Borysthenes Boscawen. Boscovich.

following, he was made rear-admiral of the blue, and commander-in-chief of the sea and land forces employed on an expedition to the East Indies. On the 4th November he sailed from St Helen's, with six ships of the line, five frigates, and 2000 soldiers; and on the 29th July 1748 he arrived at St David's, and soon after laid siege to Pondicherry. The men, however, growing sickly, and the monsoons being expected, the siege was raised, and Boscawen in his retreat displayed the skill of an able military commander. Soon afterwards he received news of the peace, and Madras was delivered up to him by the French. In April 1750 he arrived at St Helen's in the Exeter, and found that in his absence he had been appointed rear-admiral of the white. He was the next year made one of the lords commissioners of the admiralty, and chosen an elder brother of the Trinityhouse. In February 1755 he was appointed vice-admiral of the blue. On the 19th of April, sailing in order to intercept a French squadron bound to North America, he fell in with the Alcide and Lys of sixty-four guns each, which were both taken. On this occasion M. de Hocquart became his prisoner for the third time, and Boscawen returned to Spithead with his prizes and 1500 prisoners. In 1756 he was appointed vice-admiral of the white, and in 1758 admiral of the blue and commander-in-chief of the expedition to Cape Breton, when, in conjunction with General Amherst, and a body of troops from New England, the important fortress of Louisberg, and the whole island of Cape Breton were taken; services for which he received the thanks of the House of Commons. In 1759, being appointed to command in the Mediterranean, he arrived at Gibraltar, where, hearing that the Toulon fleet, under M. de la Cue, had passed the Straits in order to join that at Brest, he got under sail, and on the 18th of August saw, pursued, and engaged the enemy. His ship, the Namur of ninety guns, losing her mainmast, he shifted his flag to the Newark; and, after a sharp engagement, took three large ships and burnt two, in Lagos Bay, after which he returned to Spithead with his prizes and 2000 prisoners. On the 8th December 1760 he was appointed general of the marines, with a salary of L.3000 per annum, and was also sworn a member of the privy council. He died in 1761, in the fiftieth year

BOSCOI, or Bosci (βόσκοι), the name given to a class or tribe of monks in Palestine, who took no care about provision, but when eating time came, went into the fields and ate what they could find.

BOSCOVICH, ROGER JOSEPH, a celebrated natural philosopher, born May 18. 1711, at Ragusa, a seaport on the Adriatic. His youth appears to have been marked by no precocity of talent while he studied grammar and philosophy in the schools of the Jesuits. Among these shrewd observers, however, his docility and obedience were sufficient to procure him particular attention. In his fifteenth year, after he had gone through the ordinary course of education, he was admitted into the order, and sent to Rome. Here his studies changed their character and direction: the rules and constitutions of the order claimed his attention for two years; after which he was instructed in rhetoric, and became well versed in general literature, particularly Latin poetry.

After completing his noviciate, he was sent to the Roman college to study mathematics and physics; and it was in these sciences that his genius and abilities shone forth so conspicuously. He soon arrived at eminence, and after being exempted from the operation of a law, by which the novices were bound to teach Latin and the belles-lettres for five years before they commenced the study of theology, he was appointed mathematical professor in the Jesuit's college. For this chair he was eminently qualified, as, besides a thorough knowledge of all the modern productions in the science, he had acquired a classical severity of demonstration by studying the works of the ancient geometricians Notwithstanding his

arduous duties as an instructor of youth, it was about this Boscovich. period that he formed some of those refined and original notions which were destined to grow up into the system that afterwards became so celebrated. The animating spirit of discovery and invention led him to consider every portion of physical science; and indeed so versatile and vigorous was his mind, that we should be at a loss to specify any one portion which, within a few years, it did not comprehend, elucidate, and advance. In confirmation of this it will be sufficient to enumerate the principal subjects on which he published dissertations while he continued in the professorship. These were, the transit of Mercury over the sun, the spots in the sun, the aurora borealis, the construction of spherical trigonometry, the figure of the earth, a new telescope to determine celestial objects, the ancient arguments for the rotundity of the earth, oscillating circles; on infinites and infinitely small quantities, the motion of bodies in unresisting spaces, the aberration of the fixed stars, the inequalities in terrestrial gravity; on astronomy, on the limits of certainty in astronomical observations; on the solid of greatest attraction, the cycloid, the logistic curve lines, the vires vivæ, the comets, light, the tides, the rainbow, the calculation of fractions, the centre of gravity, the moon's atmosphere, the law of continuity, lenses and dioptrical telescopes, the objective micrometer, and the divisibility of matter. Some of these are short, but all of them contain curious and valuable matter. It is only by perusing them that we are able to discover the gradual progress of his mind, and to understand the manner in which he arrived at that theory of natural philosophy which is now known by his name.

About this time a taste for philosophical poetry was very prevalent amongst the learned, and some of Boscovich's acquaintances had laboured in it with success. Of these we may mention Father Noceti, who wrote on the rainbow and the aurora borealis, and Benedict Stay, whose poems on the philosophy of Descartes, and on the more modern philosophy, are considered as excellent examples of Latin composition. Boscovich published the works of both with annotations and supplements which display a rich fund of information and learning. By such undertakings his fame soon became widely diffused. The learned societies of many countries in Europe conferred on him unsolicited honours, and several foreign princes invited him to their courts. His opinions on various subjects of civil architecture, topography, and hydrodynamics, were solicited by Pope Benedict XIV., John V. of Portugal, and others. These applications necessarily required his presence in different states of Europe, where he never failed to enhance his reputation, and often terminated disputes which, but for his judicious interference, might have had disagreeable consequences. He was employed to correct the maps of the papal dominions, and to measure a degree of the meridian there. In this operation he was assisted by an English Jesuit named Christopher Maire. An account of their expedition was printed at Rome and Paris, and is interspersed with some curious anecdotes; but it is chiefly valuable for the detail which is given of their observations.

In 1757 he was sent to Vienna by the republic of Lucca, to settle some differences concerning the draining of a lake, in which the grand duke of Tuscany, the emperor Francis I., and that republic, were concerned; and after succeeding in the object of his mission to that city, he published there his Theoria Philosophia Naturalis in 1758. Another occasion for his mediating powers, that more nearly interested him, soon presented itself. The British government having suspected that some ships of war had been fitted out at Ragusa for the service of France, and that its neutrality had thus been infringed, the senate of Ragusa became alarmed at the suspicion, and employed Boscovich, who had often been successful in similar missions for other powers, to proceed to London, where he effected the object of his mission,

Boscovich. with honour to himself, and satisfaction to his native state. In 1760 he visited the Royal Society, which received him with distinguished marks of respect; and he soon afterwards complimented that body with a Latin poem on the solar and lunar eclipses. Boscovich was invited by the Royal Society to be of the party of their members about to procced to America in order to observe the transit of Venus over the sun's disc; but the nature of his embassy, and the necessity of returning home, prevented his accepting the invitation. Soon after his return, he was appointed by the senate of Milan to the mathematical chair in the university of Pavia, with the superintendence of the observatory of the royal college of Brera. He continued in this situation for six years, when the empress queen appointed him professor of astronomy and optics in the Palatine schools of Milan, and also requested that he would continue to superintend the observatory. Admired by the learned, beloved by his friends, and having an adequate income, with a sound and vigorous constitution, he promised to himself much happiness in the tranquil cultivation of the sciences. But a cloud long impending now burst over his head, in the edict for the abolition of his order, which took place in 1773. No exemption from the edict could be procured; all who held offices were dismissed; and Boscovich sought refuge in Paris. Thither indeed he was invited by Turgot, through whose means he was made one of the directors of optics for the sea service, and received a pension; but he never ceased to mourn his exile, and the ruin of his order. He remained there, however, for ten years, on the expiry of which he obtained leave to visit Italy; and he published at Bassano, in five volumes quarto, a collection of the works which he had completed in Paris.

> The following is a pretty accurate enumeration of their contents: A new instrument for determining the refracting and diverging forces of diaphanous bodies; a demonstration of the falsehood of the Newtonian analogy between light and sound; the algebraic formulæ regarding the foci of lenses, and their applications for calculating the sphericity of those which are to be used in achromatic telescopes; the corrections to be made in ocular lenses, and the error of the sphericity of certain glasses; the causes which hinder the exact union of the solar rays by means of the great burning glasses, and the determination of the loss arising from it; the me-thod of determining the different velocities of light passing through different media by means of two dioptric telescopes, one common, the other of a new kind, containing water between the objective glass and the place of the image; a new kind of objective micrometers; the defects and inutility of a dioptric telescope proposed and made at Paris, which gives two images of the same object, the one direct, the other inverse, with two contrary motions of movable objects; masses floating in the atmosphere, as hail of an extraordinary size, seen on the sun with the telescope, and resembling spots; the astronomical refractions, with various methods for determining them; different methods for determining the orbits of comets and of the new planet, with copious applications of these doctrines to other astronomical subjects, and still more generally to geometry and to the science of calculation; the errors, rectifica-tions, and use of quadrants, sextants, astronomical sectors, the meridian line, telescopes called transit instruments, the meridian, and the parallactic machine; the trigonometrical differential for mulæ, which are of so much use in astronomy; the use of the micrometrical rhombus, extended to any oblique position whatsoever; the error arising from refractions in using the astronomical ring for a sun-dial, and the correction to be made; the appearing and the disappearing of Saturn's ring; methods of determining the rotation of the sun by means of the spots; the greatest exactness possible in determining the length of a pendulum oscillating every second of mean time by the comparison of terrestrial and celestial gravity; a compend of astronomy for the use of the marine, containing the elements of the heavenly motions, and of the astronomical instruments, to be explained to a prince in the course of one month; a method for determining the altitudes of the poles with the greatest exactness, by means of a gnomon alone, where other instruments are not to be had; the determination of the illuminated edge of the moon to be observed on the meridian; a method of using the retrograde return of Venus to the same longitude, for determining the less certain elements of her orbit; a method for correcting the elements of a comet, of which the longitude of the node is

given, and the inclination of the orbit has been nearly found; an- Bosjesmans other method for the same purpose, and for finding the elliptical orbit, when the parabolic one does not agree with observation; a method for correcting the elements of a planet by three observations; the projection of an orbit inclined in the plane of the ccliptic; the projection of an orbit inclined in any other plane; the calculation of the aberration of the stars, arising from the successive propagation of light; and some beautiful theorems belonging to triangles, which are of great use in astronomy, reduced to the most simple demonstrations.

After the publication of these works, Boscovich quitted Bassano, and went to Rome to visit the companions of his youth. From Rome he proceeded to Milan, where he revised some of his own works, and prepared for publication the two last volumes of Stay's poems. His death took place on the 13th of February 1787, in the seventy-sixth

vear of his age.

Besides the different works above mentioned, Boscovich wrote several others on various subjects, as on the project of turning the navigation to Rome from Fiumicino to Maccarese; on two torrents in the territory of Perugia; on the embankments of the river Ponaro; on the river Sidone in the territory of Placentia; on the embankments of the Po; on the harbours of Ancona, of Rimini, of Magna Vacca, and Savona; besides some others, almost all of which were printed. For an account of the system developed in the Theoria Philosophiæ Naturalis, see the article Physics.

BOSJESMANS, or BUSHMEN, a race of Hottentots who inhabit the sides and valleys of the Sneewberg, or Snowy Mountains, which form the northern boundary of the colony of the Cape of Good Hope. They are rude and savage in the extreme, and in their persons present a caricature of that form which characterizes the Hottentot, the hollow back, protruding belly, and large buttocks. Destitute of cultivation, and inhabiting the most desolate tracts, they procure with difficulty even a scanty supply of the most wretched aliments. Wild animals, roots, and the larvæ of ants and insects, form their usual resources. To this, indeed, they add frequent predatory excursions to the storefarms in the plains; but this involves them in a severe and unequal contest, since their arrows, though tipt with deadly poison, and shot with surprising dexterity, are no match for The cruelty with which the fire-arms of the colonists. they have been pursued by the colonists still renders them extremely shy of strangers. Mr Barrow met with a young man who had made a journey along part of their territory, and who being asked if he had seen any of them, replied with an air of disappointment, that he had shot only four. Judging from the accounts of travellers who have been among them, and from the individuals of their race exhibited in this country, they appear to be by no means unsusceptible of civilization. They display nothing of that sluggish and gloomy deportment which characterizes the servile Hottentot. They bound with wonderful agility from rock to rock, either in flight or in chase of their prey; and on certain festive occasions, they give way to an extravagant gaiety, dancing whole days and nights, especially by moonlight. Even the pictures of animals which they delineate on the rocks are not altogether destitute of spirit or resemblance. See Burchell's Travels.

BOSNA SERAI, or SERAJEVO (ancient *Tiberiopolis*), a city of European Turkey, capital of the province of Bosnia, is situated on the Migliazza, 246 miles south of Buda, Lat. 43. 54. N. Long. 18. 26. E. The town is well built, occupying the declivities of several small hills, and its numerous turrets and minarets give it a rather imposing aspect. It is defended by a strong citadel, but the walls which formerly surrounded the town are now in ruins. It derives its name from the Serai or palace built by Mohammed II., and contains numerous mosques, and several Greek and Roman Catholic churches. The chief manufactures are fire-arms, jewellery, leather, and cotton and

Bosna Serai.

Bossu

Bossuet.

Bosnia || Bosso. woollen stuffs. In the vicinity are extensive iron mines. Population estimated at from 40,000 to 60,000.

BOSNIA, the most north-westerly province of Turkey in Europe, comprising Bosnia Proper, Turkish Croatia, and Herzegovina. It extends from Lat. 42. 30. to 45. 15. N. and from Long. 15. 40. to 21. 2. E., and is bounded on the north and west by the Austrian dominions, south by Montenegro and Albania, and east by Servia. Area estimated at 18,800 square miles; pop. (1844) 1,100,000. The whole province is mountainous, many of the summits reaching to the height of 6000 feet. From the nature of the soil, it is more appropriate for the breeding of cattle than the operations of the plough. The chief kind of cattle reared, are sheep in large flocks, some good horses and cows, with here and there a few buffaloes and goats. There are a few mines of copper; and formerly some of gold and silver were worked, especially a very celebrated one at Jlatnizza; but they are now neglected. Bosnia has some quarries of good marble; and at Tuzla is a very copious and strong spring of salt water, which is converted into culinary salt. The manufactures are of the domestic kind, and upon a small scale, including leather, cloth, and iron wares. Bosnia is under the government of a pasha of three tails, and is divided into six circles, and forty-eight smaller divi-

BOSPHORUS, or rather Bosporus, the name given by the Greeks to any straits. Bosporus is synonymous with the Italian faro, the Latin fretum, and the French pas or manche. The word is formed of $\beta o \hat{v}_s$, an ox, and $\pi o \rho o \hat{v}_s$, passage, probably from the idea that an ox might swim across. The origin of the name is not disputed; but various mythological legends were invented to account for its first application; as that of its having derived its name from Io, who crossed it under the form of a heifer. The name of Bosporus is chiefly confined to two straits, namely, the Bosporus of Thrace, commonly called the Strait of Constantinople, or Channel of the Black Sea; and the Cimmerian or Scythian Bosporus, now known as the Strait of Yenikalé. See Black Sea.

BOSQUETS, in *Gardening*, groves, so called from boschetto, an Italian word which signifies a little wood.

BOSSCHA, HERMANN, a distinguished scholar and antiquary, born at Leeuwarden in Friesland, March 18. 1755. After having been rector of the Latin schools at Francker and Deventer, in 1795 he was appointed to a chair in the university of Harderwyck. He was subsequently a professor at Groningen; and in 1807 he was appointed to the chair of history in the Athenæum at Amsterdam. Bosscha died on the 12th Aug. 1819. He was an excellent Latin poet, and the author of various works on classical subjects, besides translations, and a history of the revolution in Holland in 1813.

BOSSCHAERT, THOMAS WILLIBRORD, a Flemish painter, born at Bergen-op-Zoom in 1613, and educated at Antwerp under Gerard Seghers. After a residence of four years at Rome he returned to Antwerp, and acquired a high and merited reputation. His works, which are in the style of Vandyck and Reubens, are harmonious and tender in colouring, the drawing is free and spirited, and the finish is frequently exquisite. He died in 1656.

BOSSINEY, a small village in the parish of Tintagel, on the north coast of Cornwall, and consisting of little more than a group of cottages. Previous to the passing of the Reform Act it united with the small neighbouring village of Trevenna in returning two members to parliament. The ruins of a castle near it are said to be those of the palace in which King Arthur was born, and where the ancient dukes of Cornwall resided. Pop. of parish in 1851, including both villages, 1084.

BOSSO, in Latin Bossus, Matteo, distinguished by his virtue and his learning, was born at Verona in 1428. In 1451 he joined the congregation of regular canons of St

John de Lateran; and he afterwards taught divinity at Padua. His orations, sermons, and letters, have often been printed; and he also wrote a sort of apology for Phalaris, and other works. He died at Padua in 1502.

BOSSU, RENÉ LE, an eminent French critic, born at Paris, March 16. 1631. He studied at Nanterre; and in 1649 entered among the regular canons of Sainte-Geneviève. After having professed the humanities in different religious houses for twelve years, he withdrew into retirement. His first publication was Parallèle des Principes de la Physique d'Aristote et de celle de René Descartes, which appeared in 1674. He attempted, says Voltaire, to reconcile Aristotle and Descartes, not aware that it had become necessary to abandon both. His next work, entitled Traité du Poème Epique, was published in 1675, and often reprinted afterwards. Its leading doctrine is that the subject should be chosen before the characters, and that the action should be arranged without reference to the personages who are to figure in the scene. Nevertheless, Boileau, in his Third Reflexion on Longinus, pronounces this work "I'un des meilleurs livres de poétique qui, du consentement de tous les habiles gens, aient été faits en nôtre langue." In abatement of this commendation, however, it may be stated, on the authority of Le Courayer, that Le Bossu had defended Boileau against Saint-Sorlin, by whom he had been attacked; that Boileau expressed himself exceedingly grateful for this service; and that a sense of obligation may perhaps have dictated the commendation he bestowed on the work. Bossu died March 14. 1680.

BOSSUET, JACQUES BÉNIGNE, one of the most illustrious prelates which the church of France—so fruitful in great men—has ever produced, was born at Dijon on the 27th September 1627. He was descended from an ancient and noble family in Burgundy. On the establishment of the parliament of Metz, his father was appointed one of its counsellors. Being destined by his parents for the church, the young Bossuet took the clerical tonsure before he had completed his eighth year. At first he was placed under the care of his uncle, the first president of the parliament of Metz; and he used to relate that while a mere boy under his uncle's roof he read the Old Testament with a relish and delight far exceeding any pleasure he afterwards felt on the perusal of any other work. His uncle afterwards placed him at the college of the Jesuits at Dijon, where he applied himself to his studies with such labour and success that they desired to attach him to themselves; but in 1642 his uncle sent him to Paris to the college of Navarre. Here, under the direction of the celebrated Nicholas Cornet the principal, Bossuet made rapid progress in Greek and philosophy, relieving his studies from time to time by reading the best works of antiquity; but the Scriptures and religious books always occupied a large share of his time. At the age of sixteen he supported his first thesis in a manner which gave indications of his future greatness, and which caused him to be already regarded as a prodigy. An extempore sermon, which he shortly afterwards delivered at the Hotel of Ram bouillet, in presence of an assembly partly composed of the most celebrated men of the time, excited general admiration.

He was admitted into the corporation of the college at the age of twenty, on which occasion he chose for the subject of his thesis a comparison between the glory of this world and that which awaits the just in the next. During the delivery of this discourse, the great Condé, who had just dazzled France by the splendour of his victories, suddenly entered the hall, surrounded by a number of his companions in arms. The orator, without interrupting his harangue, immediately addressed himself to the young conqueror, and, in the name of France, paid him a just and appropriate tribute of admiration and praise; but he told him at the same time how vain and perishable was the glory which he had acquired. Forty years after, Bossuet repeated the same

Bossuet. truths over the bier of the princely warrior. During the whole of that long period he had enjoyed his friendship and

> In 1652 Bossuet took the degree of doctor, and received also the order of priesthood. In thus devoting himself to the cause of religion, he exclaimed, "Under thy auspices, O sacred Truth, I will joyfully approach those altars which are to witness the oath I am about to take; an oath which our ancestors have often heard; that most pleasing and most sacred oath, by which I am to bind myself, even to death, to the holy cause of truth." After passing some time in the retreat at St Lazarus under the discipline of St Vincent de Paul, whose friendship he had obtained, he went to Metz, in the cathedral church of which city he had previously obtained the preferment of a canonicate, and where he was successively raised to the rank of archdeacon and dean. He now applied himself wholly to the duties of his ministry, edifying those who surrounded him by the purity of his life, and astonishing them by the splendour of his talents. His first appearance as an author was in 1655, when he published his Refutation of the Catechism of Paul Ferry, a Protestant minister highly esteemed for his learning and talents. This work advanced his reputation greatly with his own party, and, it is said, gained him even the respect of the Protestants. The affairs of the cathedral rendering his presence necessary in Paris, he often preached there; and his sermons were so universally applauded, that he was appointed to preach in the chapel of the Louvre before Louis XIV. during the Lent of 1663. His Majesty signified the pleasure he derived from his sermons in a letter which his private secretary wrote by his desire to Bossuet's father.

> In 1669 he was nominated to the bishopric of Condom; but being appointed preceptor to the Dauphin the following year, he resigned his see, because he considered his new charge as inconsistent with the duty he owed to his diocese. For the instruction of the Dauphin he composed his work on universal history, which he divided into three parts. The first part is purely chronological; but it has been well observed that it scarcely contains a sentence in which there is not some noun or verb that conveys an image or suggests a sentiment of the noblest kind. The third part, which is historical, contains the most profound reflections on the rise "But in the second part of it," as one and fall of empires. of his biographers observes, "the genius of Bossuet takes its highest flight. He never appears on the stretch of exertion; he is never lost in the mazes of argumentation; but, in a continued strain of sublime eloquence, he displays the truths and proofs of the Christian religion with a grandeur of thought, a magnificence of language, and a force of evidence, which nothing can withstand. A nobler work in support of Christianity has never issued from the press." This work was first published in 1681. Ten years previous, he had published his Exposition of the Doctrine of the Catholic Church in Matters of Controversy, which was speedily translated into all the living languages of Europe. Pope Innocent XI. formally approved of it by two successive briefs on the 22d November 1678 and the 12th July 1679; and the Gallican clergy in their assembly of 1682 gave it also the seal of their approbation. It has therefore, we believe, been regarded as a correct exposition of the tenets of the Roman Catholic Church. The publication of the Exposition gave rise

one of the ablest divines of the Reformed church in France. Having finished the education of the Dauphin in 1681, the king nominated Bossuet to the bishopric of Meaux, and he entered with zeal upon the duties of his new episcopate. He took a very active part in the general assembly of the church of France held the following year, and drew up the celebrated declaration of 1682 against the attempted encroachments of the see of Rome. Bossuet now directed all

to the famous conference between Bossuet and Claude,

all his controversial works, the History of the Variations of Bossuet. the Protestant Churches, which was first published in 1688. Gibbon in his younger years was converted to the Roman Catholic faith by perusing this work, retiring for a while, like Chillingworth, (to use the expression of Dr Johnson in his Life of Dryden,) into the bosom of an infallible church. It has been remarked as a singular coincidence, that although no writers were ever more opposed in sentiment than Bossuet and the author of the Decline and Fall of the Roman Empire, yet the latter (c. 54) adopts and aggravates the charges made by Bossuet, in his History of the Variations, of the alleged Socinian tendency of the principles of the Reformation.

During the last years of his life Bossuet was much occupied in the hopeless scheme of effecting a union between the Roman Catholic and Protestant churches. The negotiation was first carried on with Molanus, who limited his views to a junction between the Roman Catholic and Lutheran churches, a plan which many persons considered by no means impracticable. But Leibnitz, who succeeded Molanus on the part of the Protestants, being desirous of including the whole Protestant churches in the arrangement, the negotiation failed, as might have been expected, after

a correspondence of ten years.

It was the fate of Bossuet to be involved in religious controversy during the greater part of his life. He entered the arena at the age of twenty-eight, and during the fifty years which followed, his pen was in constant requisition. He composed with ease, but, like Burke, he laboured hard to improve his writings, and did not cease to alter them till they issued from the press; yet the style of both is as free as if it had been quite spontaneous. Some of Bossuet's principal writings against the Protestants have been mentioned. He was also engaged in controversies with persons of his own communion. That with the amiable Fenelon is the most conspicuous. The mystical speculations of Madame Guyon of Port Royal having found an abettor in the person of the author of Telemachus, in a work on the maxims of the saints, Bossuet drew up his Rélation du Quiétisme, in which the archbishop was attacked with great severity. Fenelon published a reply, in which meekness, simplicity, and grandeur of mind were admirably blended. The writings in this controversy are amongst the finest in French literature; but Quietism being a perishable topic, these writings are now seldom read. In this contest the eagle of Meaux carried off the palm of victory.

Among the writings of Bossuet, his sermons and funeral orations are particularly to be distinguished. Of the latter, the finest is that on the death of Henrietta-Anne, the daughter of our Charles I. and wife of the Duke of Orleans. As his funeral orations place him in the first class of orators, so his sermons unquestionably rank him in the first line of preachers. It has been observed that Bourdaloue and Massillon alone can dispute his pre-eminence. In the opinion of Voltaire, the eloquence of Bossuet stands unrivalled. This great prelate died on the 12th of April 1704, in the 77th year of his age. Massillon and other French writers have eulogized the talents and virtues of Bossuet in terms of the highest admiration: and he is thus noticed by the Reverend Mr Eustace in his Classical Tour: "Bossuet was indeed a great man, and one of those extraordinary minds which, at distant intervals, seem as if deputed from a superior region to enlighten and astonish mankind. all the originality of genius, he was free from its eccentricity and intemperance. Sublime, without obscurity—bold, yet accurate-splendid, and yet simple at the same time,he awes, elevates, and delights his readers, overpowers all resistance, and leads them willing captives to join and to share his triumph. The defects of his style arise from the imperfection of his dialect. And perhaps he could not the energies of his powerful mind to the most important of have given a stronger proof of the energies of his mind

than in compelling the French language itself to become the vehicle of sublimity. His works, therefore, are superior to all other controversial writings in his own or any other language." His works were collected and published soon after his decease in twelve volumes quarto. The Benedictines of St Maur published another edition; but a more complete edition, in forty-three volumes octavo, was published in 1815–20. Cardinal de Bausset wrote a history of the life of Bossuet, which was published in four

321122

volumes octavo. (J. B—E.)
BOSSUT, CHARLES, an eminent French mathematician, born at Tarare, near Lyons, August 11. 1730; died January 14. 1814. He was the friend and associate of Condorcet, D'Alembert, Bailly, and Lavoisier. His principal work is entitled Traits Elementaire de Mecanique et de Dynamique.

BOSTON, a parliamentary and municipal borough and seaport town of England, in the county of Lincoln and wapentake of Skirbeck. It is situated in a rich agricultural district on the Witham, six miles from the sea, and 28 miles S.E. of Lincoln. Lat. 52. 59. N. Long. 0. 2. E.

Boston is by some supposed to have been a Roman station in the province of Slavia Cæsariensis, of which Lincolnshire formed a part, but of this sufficient evidence does not seem to exist. According to the Saxon Chronicle, St Botolph, the patron of sailors, founded a monastery at Icanhoe in 654, which was destroyed by the Danes in 870. From this Boston is said to have taken its name (Botolph's town). It became a place of considerable commercial importance after the Norman conquest, and, in 1204, when the quinzieme tax was imposed on the ports of England, that of Boston amounted to L.780, and was exceeded only by that of London, which was L.836. A great annual fair was held at Boston about this time. By 27th Edward III. it was made a staple for wool, woolfells, leather, and lead. Its prosperity about this time induced merchants from the Hanseatic and other Continental commercial cities to settle here, who, however, about a century later, were obliged to leave, in consequence of a quarrel with the townsmen. From this time it rapidly declined. The dissolution of the monasteries by Henry VIII. injured the town, though compensation was in some degree made by granting the town a charter of incorporation, and Philip and Mary endowed it with upwards of 500 acres of land. It afterwards suffered from the plague and from inundations, to which its low situation rendered it particularly liable. During the civil wars it was for some time the headquarters of Cromwell's army.

Boston is well built, paved, and lighted, and contains many good dwelling-houses, shops, and warehouses. It is divided into two nearly equal parts by the Witham, here crossed by an elegant iron bridge of one arch 86 feet in span. Until recently the supply of water was very deficient, but in virtue of an act passed in 1847 it has now a plentiful supply conveyed by pipes from a distance of twelve miles. The principal building is the parish church of St Botolph, founded in 1309. It is one of the largest churches without aisles in the kingdom, being 290 by 98 feet within the walls. The tower, 290 feet in height, resembles that of Antwerp cathedral, and is crowned by a beautiful octagonal lantern, forming a landmark seen forty miles off. There is a chapel of ease, erected in 1822, and chapels of Independents, Methodists, Baptists, &c.; a free grammar-school, founded in 1554, Laughton's charity school for the sons of poor freemen, a bluecoat, national, infant, Sunday, and other schools. There is also a dispensary, a town-hall, market-house, assembly rooms, theatre, borough gaol, house of correction, union poor-house, Vauxhall, mechanics' institution, public baths, two subscription libraries, custom-house, four banks, and a savings-bank. The manufactures consist chiefly of sail-cloth, canvass, sacking, ropes, beer, leather, hats, and bricks. There are also two iron and

brass foundries, and three ship-yards, with patent slips, Boston. where vessels of 200 tons are built.

From neglect to clear the river, it became so obstructed that in 1750 a sloop of forty or fifty tons could with diffi culty come up to the town at spring tides. Since that period great improvements have been made, and vessels of 300 tons are enabled to unload in the town. The foreign imports are chiefly timber, pitch, tar, and hemp from the Baltic, and coal and manufactures coastwise; the exports, wool, wood, corn, and other agricultural produce. In 1849 there belonged to the port 177 sailing vessels of 8377 tons, and two small steamers; 1253 vessels of 60,298 tons entered, and 570 vessels of 24,622 tons cleared; customduty received, L.31,355. By means of the river and the canals connected therewith, Boston has a navigable communication with Lincoln, Gainsborough, Nottingham, and Derby. The East Lincolnshire railway connects it with Louth, Grimsby, and other towns in the north, and the Great Northern with Peterborough and the south; another line extends to Lincoln. Market-day, Wednesday. Boston is divided into two wards, and is governed by a mayor, six aldermen, and eighteen councillors. It has returned two members to parliament since the reign of Edward IV. Registered electors (1851-52), 987. Population (1851) within the parliamentary boundaries, 17,518; within the municipality, 14,733.

Boston, the second commercial city in the United States of North America, and capital of the state of Massachusetts, is situated at the head of Massachusetts bay, near the confluence of the Charles and Mystic rivers, 207 miles N.E. by E. from New York. Lat. 42. 21. 23. N. Long. 71. 4. 9. W. It takes its name from the cognominal town in England, whence many of its original settlers had emigrated. They established themselves, in 1630, on the small peninsula, of about 600 acres in extent, connected with the continent by a narrow isthmus, and now known as Old Boston. As early as 1740, it was a place of some importance, and distinguished for its commercial enterprise, particularly in ship-building and the fisheries. Its population was then 17,000. For more than half a century, its progress was checked by the Indian, French, and English wars, and the restrictive policy of England; so that in 1790 its population amounted to only 18,038. Boston took the lead in opposing those obnoxious duties that resulted in the independence of the States, and suffered severely during the revolution, from the effects of which its recovery was slow: its stores and public buildings had been injured or burned down, and its commerce entirely ruined. Since 1790, however, it has made rapid advances in trade and commerce. The original limits were soon found inadequate for the growing town; and the state in 1804 annexed to it Dorchester Point, another peninsula of about the same extent, and which now constitutes South Boston. At a later period Noddles Island, having an area of 660 acres, was included within the bounds of the city, forming what is now called East Boston. Some hundred acres have also been reclaimed from the sea. Though the chartered extent of the city is thus small, being only about three square miles, its real limits are much more considerable; and, indeed, the population outside its chartered boundaries is at least equal to that within. If we include the numerous towns and villages in the suburbs, where many of the merchants and others of the city reside, and which the numerous omnibuses and railways render easy of access, the population will be much more considerable. The following are the decennial populations since 1790: -in 1800, 24,937; 1810, 33,787; 1820, 43,298; 1830, 61,392; 1840, 93,383; and 1850, 138,788. The population of the district within a circuit of nine miles from the exchange, and of which about one-fourth is occupied by water, marsh, or rocky hills too steep for building, amounted in 1850 to 269,874.

Boston.

The Peninsula of Old Boston was originally called Shawmut, or Trimountain, from its springs and three lofty hills. These last have been to a great extent preserved, and being covered with buildings, give a picturesque appearance to the city. The streets, however, having been originally laid out upon no systematic plan, and accommodated only to the nature of the ground, are in general crooked and narrow. though modern improvements have greatly remedied these inconveniences. The houses are generally of brick, but large and well built. The numerous eminences, rising from 50 to 110 feet above the level of the sea, furnish many admirable sites for building, and many of the private residences are unsurpassed in elegance and taste by those of any other city in the Union. Numerous bridges open communication in various directions for Old Boston. The principal of these are—the Charles river bridge, 1503 feet long, connecting Boston with Charlestown; West Boston bridge, 2758 feet, with a causeway of 3432 feet, leading to Cambridge; South Boston bridge, 1550 feet, from the "neck" or isthmus to South Boston; Canal bridge, 2796 feet, to East Cambridge, from the middle of which an arm extends to States Prison Point in Charlestown; Boston free bridge, 1828 feet, to South Boston; Warren bridge, 1390 feet, to Charlestown. The Western avenue leading to Brookline is a solid structure 7000 feet long, faced with granite on each side, and filled up with earth; and constitutes a tidedam inclosing a pond of 600 acres.

South Boston is united to Old Boston by four bridges, and is regularly laid out into streets and squares. In the centre are the "Dorchester Heights," 130 feet high, famous in the revolutionary war as the site of a fortification which compelled the British to abandon the harbour.

East Boston is connected with the old town by a ferry, and with Chelsea on the mainland by a bridge. This portion of the city has taken its rise since 1833. A wharf 1000 feet long is devoted to the use of the Liverpool steamers.

Boston, with the town of Chelsea, constitutes he country of Suffolk. It is divided into twelve wards; and is governed by a mayor 8 aldermen, and 48 councillors, all chosen annually by the citizens. Besides these, each ward has a warden, an overseer of the poor, a clerk, 5 inspectors, and 2 school committee men. There is a police court of three justices, for the trial of minor offences and the examination of criminal charges; as well as a municipal court, held by a single judge, with jurisdiction in all criminal cases not capital.

Among the public buildings of Boston the principal is the State house, a large and commodious edifice on Beacon Hill. 110 feet above the level of the sea, and fronting the "common." It was erected in 1798, and is 173 feet long, by 61 wide, built of brick, but painted so as to imitate stone. It is ornamented by two iron fountains, and has a fine dome 52 feet in diameter, with a cupola 230 feet above the level of the harbour, from which a magnificent view is obtained. Faneuil Hall, an ancient brick edifice, 100 feet long, by 80 wide, and three stories high, is celebrated as the spot where the revolutionary orators roused the people to resistance. Faneuil Hall market is an elegant granite building 536 feet long, 50 feet wide, and two stories in height. The city hall or old state house is another venerable edifice of revolutionary memory, and now used for public offices. The Massachusetts general hospital is a beautiful granite structure 168 feet long, by 54 wide, surrounded by four acres of ground on the bank of the Charles river. The custom-house is a splendid granite building of Grecian architecture. Among the other public buildings are the Massachusetts eye and ear infirmary; the institute for the blind at South Boston; the orphan asylum; the merchants' exchange; the athenæum; a club-house in the Italian style; three theatres; a museum; two large buildings for concerts and lectures; and a quarantine hospital at Rainsford Island. An extensive jail, and a spacious alms-house have recently been erected. In the vicinity are two large and elegant town houses of Denham and Cambridge; the Quincy market, a granite structure 500 feet

by 38; the Quincy town house; a collegiate building at Newton; the Harvard university buildings, an observatory, and a

lunatic asylum at Cambridge.

The "common" is a beautiful park in Old Boston, encircled by an iron fence; the public garden is well laid out, and contains 14 acres. Several of the squares and areas are embellished by public fountains. Although originally well supplied with water by natural springs, these soon proved insufficient for the wants of the town, and in 1795 pipes were laid by a private company for bringing water from Jamaica pond, 5 miles from the exchange. This source also proving inadequate, a new aquednet was constructed for supplying the city with water from Cochituate lake, 20 miles distant. This was commenced in 1846, and opened for use in October 1848. The water is brought by a brick conduit of an elliptical form, measuring 6 feet 4 inches by 5 feet, to a large reservoir in Brookline, covering an extent of 22 acres, and capable of containing 100,000,000 gallons. From Brookline the water is carried in large iron pipes for 5 miles to two large reservoirs, one on Beacon Hill holding 2,500,000 gallons, and the other on Dorchester Heights, South Boston, holding 6,000,000 of gallons, and each about 120 feet above the level of the sea. From these it is sent through the city by 70 miles of pipes, and is also conducted in pipes to East Boston. In 1831 Mount Auburn, in Cambridge, a spot remarkable for its natural beauties, was selected for a rural cemetery. It extends over 118 acres, and is tastefully laid out, containing a chapel, and many elegant marble monuments. There is another handsome cemetery at Forest Hill, Roxbury, and one or two others are in the course of formation. Few interments are now made within the city. The wharfs of Boston are extensive, and all lined with continuous rows of warehouses. Long Wharf is 1800 feet long and 200 wide; Central Wharf 1379 feet long and 150 wide; India Wharf 980 feet long; Granite, Commercial, and Lewis's Wharfs are of similar size. The warehouses are numerous and large, many of them four or five stories high, and extending backwards from 60 to 100 feet.

The religious and charitable institutions of the city are numerous and well supported. It has nearly 200 churches and places of worship, some of which, as Trinity and St Paul's churches, are elegant edifices. There are also a general hospital, 2 lunatic asylums, a blind asylum, an eye and ear infirmary, a maternity hospital, an orphan asylum for girls,

and a farm school for boys.

Boston has long been celebrated for the number and excellence of its schools and literary institutions. The medical branch of Harvard University has its seat here. The athenaum occupies two large buildings, the one containing a library of about 30,000 volumes; the other a picture gallery, a hall for public lectures, and other rooms for scientific purposes.

In 1850 there were 178 primary schools, with 11,376 scholars, and 22 large grammar-schools, with 9154 scholars, besides other schools with 471 scholars. The teachers of the primary schools receive a salary of \$300, and the masters of the grammar-schools \$1500 per annum. Boston has also a Latin and a high school, in which the higher branches are taught. These schools are open to all classes free of charge. Without the chartered limits are Harvard University, with its law and theological schools, a Baptist college, and many excellent schools and aca-

demies. See Massachusetts.

Among the literary societies are the American Academy of Arts and Sciences, the Massachusetts Historical Society, and the Boston Natural History Society. Deserving of particular notice among the literary institutions of Boston is the Mcrcantile Library Association. There are now several of these in the United States, but Boston has the honour of having taken the initiative in their establishment. As the name indicates, it is chiefly intended for the mercantile classes of the community; but the public generally are admitted as members, although on somewhat different terms. Its object is to prepare those of the rising generation who are to be the future merchants of the city, to assume that position with credit to themselves and honour to their country. It has a library, reading-room, classes, and lectures, with a gymnasium and riding school. The library contains about 16,000 volumes, and the annual addition is upwards of 2000. The annual subscription is only two dollars. In 1852 it had 2215 members; the income was \$7559, and the expenditure \$5806. The present premises have been found inadequate, and a new edifice is about to be erected, at the cost of from \$50,000 to \$60,000. The

Boston

Boswell.

Boston. athenaum library, the Boston and mercantile library, the law library, the state library, and the several libraries of Harvard University, contain together more than 150,000 volumes. There are 80 periodicals and newspapers published in Boston, in almost all departments of literature and science. Among these is the North American Review, which has long had a high reputation.

The harbour of Boston is one of the best in the United States, being spacious, safe, and easily defended. It is landlocked, accessible to ships of the line, and rarely if ever obstructed by ice. At the N. entrance, Lat. 42. 20. N. Long. 70. 54. W., is a lighthouse, with a revolving light 90 feet above the level of the sea. The passage is so obstructed by islands as to be barely sufficient for two large vessels to sail abreast. It is effectually commanded by two large fortresses on George's and Castle Islands, constructed with all the improvements of modern science: a third, the Citadel, on Governor's Island, is in the course of construction. From Point Alderton to Medford, the harbour is 14 miles in length, and from Chelsea to Hingham, 8 miles in width, covering an area of 75 square miles, and capable of containing all the ships of the Union. The bay contains numerous small islands, many of which afford excellent pasture. The United States have expended large sums on their fortresses and arsenal, extensive navy-yard, dry dock, rope-walks, stores of cannon, arms, and other materials, cus tom-house, and hospitals for sick and infirm seamen. All these are situated on Boston harbour, and are valued at eight millions of dollars.

In 1852, 381,088 tons of shipping belonged to the port of Boston. The arrivals from foreign ports in 1850 were 2877 vessels, of the aggregate burden of 478,859 tons, and the clearances for foreign ports, 2839, of 437,760 tons. In 1849-50, 23,480 tons of shipping were built. The foreign arrivals in 1852 amounted to 2864, and the clearances to 2863 vessels. In that year the coastwise arrivals and clearances, so far as known—those laden with wood, stone, and sand not reporting at the custom-house-were, arrivals 6286, clearances 3291. The value of foreign imports for 1849 was \$24,117,175; exports, \$8,843,974; duties, \$5,031,995; for the first half of 1850, imports, \$16,329,501; exports, \$4,426,216; duties, \$3,126,472.

The reports of the trade of Boston for 1852 indicate a considerable and healthy increase. The following list shows the state of trade in some of the principal articles during the years 1851 and 1852. The receipts include goods brought into the town, either by sea or by railway: besides the exports, large quantities of many of the articles are sent out by railway.

damming	Or III	anily or one	ar mores c	me semi our	Dy Latti	ay.

It has also an extensive trade in iron, tobacco, sugar, molasses, oils, leather, dye-woods, &c. Immense quantities of ice are sent to South America, the East and West Indies, China, and other parts. Although the number of tons exported in 1852 was somewhat less than that of 1851, it much exceeded that of any preceding year; being in 1848, 57,507; 1849, 66,308; 1850, 69,623. The ice is chiefly brought by railway from Wenham, and the other lakes near Boston. Large cattle markets are held weekly at Brighton and Cambridge, in the vicinity. The rapid growth of Boston and its environs during the last ten years, is undoubtedly to be attributed, in a great measure, to the establishment of the numerous lines of railway, affording it facilities of commerce with the interior. In 1839 there were only 167 miles of railway radiating from Boston, while in 1850 it was connected with 1000 miles of railway in Massachusetts, and about 2000 in other states. miles of the exchange, seven railways branch into sixteen; and two hundred and forty trains enter or leave Boston daily.

In Boston there are thirty-two banks, three savings-banks, numerous mutual assurance companies, and several foreign agencies. The assessed valuation of property in 1853 was, real, \$116,090,900, personal, \$30,423,300; and the amount of tax, \$1,569,507. The amount of city debt at 1st January 1853 was \$1,746,510, to meet which there were specially appropriated to that object, bonds, notes, and mortgages, amounting to \$1,007,689, besides the public lands and other disposable property of the city.

Boston was the birthplace of Dr Benjamin Franklin. (Hunt's Merchants' Magazine; De Bow's Industrial Resources of the South and West; Gazetteer of the United

States, &c.)

Boston, Thomas, a popular and learned Scottish divine, born at Dunse, May 17. 1676. He was educated at Edinburgh, and in 1699 became minister of the parish of Simprin, from which he was translated in 1707 to Ettrick. He died May 20. 1732. His writings were numerous; but he is best known by his Fourfold State, the Crook in the Lot, and his Body of Divinity, a work much esteemed by Presbyterians. His treatise on Hebrew accents is a learned production; and, besides many other works, he also left Memoirs of his own Life and Times, published in 1776.

BOSWELL, James, Esq. of Auchinleck, in the county of Ayr, was the eldest son of Alexander Boswell, Lord Auchinleck, one of the judges of the supreme courts of session and justiciary in Scotland. He was born in 1740, and successively prosecuted his studies at the universities of Edinburgh and of Glasgow. He was destined by his father for the bar; and, as the study of civil law at one of the foreign universities was then included in the most liberal plan of education for a Scottish advocate, it was determined that he should repair for that purpose to Utrecht, with a permission, before his return, to make the tour of Europe.

He was very early ambitious of being admitted into the society and friendship of men distinguished by talent and public estimation, more especially those of eminence in the literary world; and his natural urbanity, as well as gaiety of disposition, rendered it no difficult matter to gratify this propensity. While at the university of Glasgow, he had formed a particular intimacy with Mr Temple, the friend of Gray, afterwards vicar of St Gluvias in Cornwall; and he was known to many of the conspicuous characters at that time in Scotland, among others, to Lord Kaimes, Lord Hailes, Dr Robertson, and Dr Beattie. But the most remarkable acquisition which he made of this kind was his acquaintance with Dr Johnson, which commenced in 1763, and proved at once the principal era in his own life, and the means of adding not a little to the fame of that great man.

Boswell had visited London for the first time in 1760, when he accidentally became acquainted with Derrick, afterwards King Derrick, as the master of ceremonies at Bath was then fantastically titled, and by him was initiated into the arcana of London life. In 1763 he proceeded to Utrecht. Having passed a year at that university, he travelled into Germany and Switzerland, was entertained by Voltaire at his castle of Ferney, and conversed with Rousseau in the solitudes of Neufchatel. He continued his route to Italy; but, led by his natural enthusiasm, forsook the common lines of travel, and passed over to Corsica, which, after a contest of more than thirty years, was still struggling for independence with the republic of Genoa. Of his visit to this island he published a narrative on his return to Scotland, entitled An Account of Corsica, with Memoirs of General Pasquale de Paoli, Glasgow, 1768. It was translated into Dutch, German, French, and Italian. He likewise printed, in the following year, a collection of British Essays in favour of the Brave Corsicans; and made such attempts as he could to interest the British government in favour of that people, before they were finally crushed by the pressure of the French arms. His friendship with General Paoli was afterwards renewed in London, when that chief, having escaped with difficulty from his native isle,

Market

Botal.

Boswell. found an asylum in the British dominions. From Corsica he repaired to Paris; and, returning to Scotland in 1766, he was admitted to the bar. Soon after, he published a pamphlet on the Douglas Cause; written while that great suit was depending in the Court of Session, with a view to excite the public interest in favour of Mr Douglas. 1769 he was married to the daughter of David Montgomery, Esq.; an accomplished lady, in whose society he enjoyed every domestic happiness. By her he had two sons and three daughters.

In 1773 Boswell was admitted into the Literary Club, which then met at the Turk's Head in Gerard Street, Soho, and of which Dr Johnson had been an original member. Here he had the pleasure of associating with Burke, Goldsmith, Reynolds, Garrick, and other eminent persons. Dr Johnson had long projected a tour to the Hebrides; and Boswell at last prevailed upon him, in the course of this year, 1773, to put the plan in execution, and became the companion of his journey from Edinburgh. During this excursion they saw whatever was most remarkable in the Western Highlands and Isles; and Boswell, alive to the advantages which he enjoyed, improved every opportunity of knowledge and remark, and has preserved a faithful record of all. Both travellers gave to the world an account of this tour. Boswell's Journal was published in 1785.

In 1786 Boswell removed with his family to London, towards which, as a great centre of literature and life, his inclinations had always tended. He had recently been called to the English bar. He did not, however, prosecute the profession, but gave himself up to his natural bent for society and letters. After Dr Johnson's death, iu 1784, he was occupied for several years in collecting and arranging, with indefatigable diligence, the materials for a narrative, which he had long projected, of that eminent man's life. This most unique and valuable work was published in two vols. 4to, London, 1791.

Besides the works already mentioned, he was the author of two political Letters addressed to the People of Scotland.

Mr Boswell died on the 19th June 1795. In his private character he was loved by his friends, and was a favourite in the circles of social life. His talents would probably have been rated higher if they had not been obscured by certain eccentricities of character; yet his writings bear sufficient testimony to his natural abilities, and to the delicacy as well as aptness of his intellectual touch. To be distinguished was his ruling passion, and he indulged it freely. He sought those whom the world, on whatever account, held in honour; and he was desirous of being known as one who possessed their friendship. He was fond of his pedigree and family connections, and he aspired after literary fame. While some of these propensities have been common to the great and good in every age, others, it must be confessed, are more frequently harboured than avowed. Boswell adopted the latter and more unusual course. He fairly owned his passion, and, if not thus secured from attack, had all those advantages, at least, which are gained by complete ingenuousness. Nor was evidence of a substantial sort wanting to show the independence of his mind. For, however ambitious of exalted patronage, he was neither an instrument of party nor a server of the time. Of Dr Johnson's sincere attachment to him there are many and unequivocal proofs in their correspondence.

But it is not on account of his private character, or of a certain domestic celebrity which he enjoyed during his life, that he is here commemorated, but as an author, and parti-

cularly as a writer of biography. Here he is almost an in- Bosworthventor; he has at least carried this species of composition to a degree of accuracy and detail formerly unattempted. "Homer," says Mr Macaulay (Essays, vol. i.), "is not more decidedly the first of poets, Shakspeare is not more decidedly the first of dramatists, than Boswell is the first of biographers. He has no second. He has distanced all competitors so decidedly that it is not worth while to place them. Eclipse is first, and the rest nowhere." Boswell paints the whole man, presents the incidents of his life in their actual order of succession, and preserves him as it were entire; fulfilling in the history of the moral, what Bacon has assigned to philosophy as her genuine work in that of the natural world, faithfully to return its accents and reflect its image, not to add anything of her own, but to iterate only and repeat. For the task of writing Johnson's life he was peculiarly qualified. He had lived in intimacy with the sage for a period of twenty years, had early conceived the plan of such a work, and received from Johnson himself, to whom his intention was known, many particulars of his early life and personal history. Johnson's conversation is the matter of the book; and, as the philosopher did not, in the midst of his studies, give up the advantages of society, there was in his discourse a range and diversity of subject not often found in combination with classical knowledge and habits of profound thinking. Nor does this work exhibit a series merely of witty and sententious sayings: it is interspersed alike with miscellaneous narrative and criticism; and, what constitutes its principal feature, it contains a mass of opinions on subjects of a more common nature, where the powers of reasoning and illustration are applied to familiar topics, and the ordinary occurrences of life. Valuable as a deposit of literary anecdote, it is still more so as a collection of ethical discourses, to which its popular form gives a singular currency and effect; so that there are few books extant where the religious and social duties, as well the love of science, in its largest acceptation, are impressed more agreeably, or with greater force, upon the mind.

BOSWORTH-MARKET, a market-town and parish of England, county of Leicester, and hundred of Sparkenhoe, 11 miles west of Leicester, and 106 from London, near the North-Western railway and the Ashley canal. The town is neatly built, occupying an eminence in the centre of a fertile district, and has a handsome church surmounted by a spire, several charities, and a well-endowed grammar-school, in which Dr Johnson was once an usher, and which has two fellowships and four scholarships in Emmanuel College, Cambridge. Pop. (1851) 1058; many of whom are employed in the knitting of worsted stockings. Marketday, Wednesday. Near the town was fought (22d August, 1485) the decisive battle in which Richard III. was slain.

BOTAL, or BOTALLI, LIONARDO, a celebrated physician, was a native of Asti in Piedmont, and flourished in the latter part of the sixteenth century. After studying under Fallopius he went to France, where he was appointed chief physician to Charles IX., and also to the Duke of Alençon, whom he accompanied to England. Subsequently he was physician to Henry III. Botalli, relying on the authority of Hippocrates, Galen, and the Arabian physicians, carried the practice of blood-letting to an extent that occasioned much animadversion, and perhaps with justice. He made some valuable contributions, however, to the science. The best editions of his several medical and surgical works is that published by Van Hoorne at Leyden, 1660, 8vo.

^{1 &}quot;Egotism and vanity," says he, in his Letter published in 1785, "are the indigenous plants of my mind: they distinguish it. I may prune their luxuriancy, but I must not entirely clear it of them: for then I should be no longer as I am, and perhaps there might be something not so good."

BOTANY.

THE term Botany is derived from the Greek word Botávy, meaning an herb or grass. As a science it includes everything relating to the vegetable kingdom, whether in a living or in a fossil state. Its object is not, as some have supposed, merely to name and arrange the vegetable productions of the globe. It embraces a consideration of the external forms of plants-of their anatomical structure, however minuteof the functions which they perform—of their arrangement and classification—of their distribution over the globe at the present and at former epochs, and of the uses to which they are subservient. It examines the plant in its earliest state of development, when it appears as a simple cell, and follows it through all its stages of progress until it attains maturity. It takes a comprehensive view of all the plants which cover the earth, from the minutest lichen or moss, only visible by the aid of the microscope, to the most gigantic productions of the tropics. It marks the relations which subsist between all members of the vegetable world, and traces the mode in which the most despised weeds contribute to the growth of the mighty denizens of the forest. It is a science,

then, which demands careful and minute investigations-re- Botany. quires great powers of observation and research, and is well fitted to train the mental powers to vigorous and prompt

Botany may be divided into the following departments:-1. Structural Botany, having reference to the anatomical structure of the various parts of plants, including vegetable Histology, or the microscopic examination of tissues. 2. Morphological Botany, or the study of the form of plants and their organs; these two departments are often included under the general term of Organography. 3. Physiological Botany, by some termed organology, the study of the life of the entire plant and its organs, or the consideration of the func-tions of the living plant. 4. Taxological Botany, or the ar-rangement and classification of plants. 5. Geographical Botany, the consideration of the mode in which plants are distributed over the different quarters of the globe. 6. Palæontological Botany, the study of the forms and structures of the plants found in a fossil state in the various strata of which the earth is composed.

PART I.

STRUCTURAL AND PHYSIOLOGICAL BOTANY:

VEGETABLE ORGANOGRAPHY AND PHYSIOLOGY.

This division includes a consideration of the minute structure of the various parts of plants, of the changes which they undergo during their growth and development, of the forms which they assume, and of the functions which they perform. It is the foundation of the science, and without a thorough knowledge of it there can be no correct ideas in regard to classification.

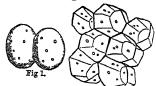

CHAPTER I.

ELEMENTARY TISSUES OF PLANTS.

I.--GENERAL REMARKS ON MICROSCOPIC VEGETABLE STRUCTURE.

The study of the elementary tissues of plants is included under Vegetable Histology (ioros, web or tissue). These tissues are few and simple. They consist of organs to which the names of Cells and Vessels have been given. The for-

mer are minute bladders or vesicles (Fig. 1), varying in size and form, which, when united together, constitute Cellular tissue (Fig. 2); while the latter are closed tubes of an elongated form, frequently tapering to each frequently tapering to each end (Fig. 3), and, when combined, constituting Vas-cular tissue. The distinction the pith of the Elder, the cells are dodecahedral and dotted.

between cells and vessels is founded on their comparative length. Occasionally, however, cells become lengthened, as in the case of some hairs, and the filamentous or thread-like tissue of Fungi, so as not to differ from vessels as regards length. VOL. V.

Such long cells are distinguished chiefly by the thinness and delicateness of their texture.

The primary form of the elementary organs of plants is a closed spherical or elongated vesicle or utricle, having its walls composed of a membrane, and containing a fluid. If it still remain closed after its development is completed, then it receives the name of Cell; but if a row of utricles arranged in lines become united in the course of development so as to form a tube with an uninterrupted cavity by absorption of the cross walls, then a Vessel is produced.

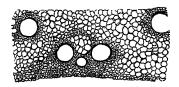

On making a transverse section of a succulent stalk, such as that of Rhubarb, or of a Cucumber or Melon, we perceive, by the aid of a glass, circumscribed angular meshes and rounded openings; and, in a longitudinal section of the same stalk, similar meshes are also seen with long tubes of various kinds. The angular spaces, as seen in Figure 4, are sections of cells, while the rounded openings are the sections of vessels. The membrane forming the walls of both cells and vessels is composed of a substance called Cellulose, in many respects resem-Vascu'ar tissue. bling starch, but differing in giving a yellow in place of a blue colour, with iodine. The membrane has in general no visible pores or

perforations, but fluid matters pass through it other. easily. Some plants, such as Sea-weeds, Mushrooms, and Lichens, consist of cellular tissue alone, and hence are called Cellular plants; while others, such as ordinary flowering plants, consist of cells and vessels combined, and receive the name of Vascular plants.

Botany.

In studying the minute structure of plants, it is necessary to call in the aid of the microscope. A simple microscope is the most useful instrument for a botanical student.

means of it the object is viewed directly through a lens or set of lenses, so arranged as to be capable of being adjusted by means of a screw to the exact focal distance, and of being moved over

different parts of the Section of a Bamboo, showing an angular net-object. In examining work of cells, and rounded tubes or vessels. structures in the fields, Gairdner's portable microscope 1 is the best. In the study of very minute tissues, and especially in physiological researches, the achromatic compound microscope is required, by means of which the object is not viewed directly, but an image of the object is formed by one lens, or set of lenses (the objective), and the picture thus produced is viewed as an original object through another lens or set of lenses (the ocular or eyepiece). By means of this instrument the observer is enabled to approach very close to the object, while the field of vision is greater than with the simple microscope.

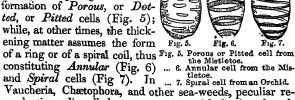

II.—CELLS AND CELLULAR TISSUE.

1. Anatomy of Cells.

Cellular tissue (Fig. 2) is generally called Parenchyma (πορὰ, through, and ἔγχυμα, anything poured in—applied to tissue), and it also receives the names of Areolar, Utricular, and Vesicular tissue. It exists more or less in all plants, and abounds in fleshy roots, stems, and leaves, and in succulent fruits. It constitutes the pith and outer bark of trees, and the central part of rushes. Chinese rice-paper consists of the central cellular tissue of Aralia papyrifera, cut into thin sheets, which show structure under the microscope. By cultivation, the turnip, carrot, cabbage, and other esculent vegetables, acquire much cellular tissue, and become tender and succulent. The bladders or cells of which the tissue is composed, vary in size. In a cubic inch of a leaf of the carnation, there are said to be upwards of three millions of cells. They are frequently seen 1000th, 500th, and 300th of an inch in diameter. In some of the cucumber tribe, and in the pith of aquatic plants, large cells, 30th and 30th of an inch in diameter, occur. Mohl says, that the general average diameter of cells is $\frac{1}{20}$ th to $\frac{1}{100}$ th of a line; that of the cellular spores of Fungi and of the yeast cells, is $\frac{1}{600}$ th of a line; while in succulent plants, and in the pith of the Elder, it rises to to to a line or more.

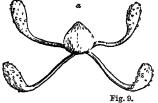

Cells are either surrounded by a simple thin membrane, or by thickened walls. The thickening of the walls of cells takes place by a deposit of woody matter on the inside, as seen in the microscopic structure of the hard shell of the Coco-nut and Piassaba fruit, in the stone of the peach and cherry, and in the seed of the Ivory and Date palms. Occa-

sionally, rounded portions of the cell-wall are left uncovered by deposits, giving rise to the formation of *Porous*, or *Dot*ted, or Pitted cells (Fig. 5); while, at other times, the thickening matter assumes the form Fig. 5.

like filaments (Fig. 8) which exhibit a vibratile motion re- Botany. sembling that of the cilia of animal mucous membranes. In Equisetum or Horsetail, there are reproductive cells, surrounded by two filaments, with thickened clavate or club-shaped extremities (Fig. 9), which are remarkably hygrometric, and exhibit movements when Cell with vibratile filaments from Chetophora.

Spore or reproductive cell of Equisetim, Horsetail, with two clavate hygrometric filaments; α the filaments expanded in a dry state; b, the filaments curled round the spore on the application of moisture.

When formed of cells composed of a homogeneous or uniform membrane, the tissue is called Membranous cellular tissue; when of spiral cells it is denominated Fibrous cellular tissue, or Inenchymu (ives, fibres). Elongated cells or tubes, with pointed extremities, when united together, form the tissue called Prosenchyma. The membranous walls of some elongated cells occasionally unrol in a spiral manner. Spiral cellular tissue exists in many Orchids; also in the cells of Sphagnum, the hairs of Cactaceæ and the seed-coat of Casuarina, in the outer covering of the seed of Collomia linearis, and of the fruit of Salvia verbenaca, or wild Clary. The spiral cells in the last two mentioned cases, when placed in water under the microscope, exhibit interesting movements, owing to the solid spiral fibre rupturing the softened membrane of the cell, and expanding in all directions. The spongy elastic character of the outer cellular covering of the roots of tropical Orchids and Araceæ, of the sepals of Illecebrum verticillatum, of the pericarp of Cachrys Morisoni and C. odontalgica, and of the ribs of the fruit of Æthusa Cynapium, is due to the presence of spiral cells. In the reproductive cells of Liverworts, spiral fibres called Elaters are found. Reticulated or netted cells, caused by fibres forming a sort of mesh or network, occur in the wing of the seed of Swietenia, in the pericarp of Picridium tingitanum, and P. vulgare, in the seed-coat of Cucurbita Pepo, in the parenchyma of the leaf of Sanseviera guineensis, and in isolated cells of the pith of Rubus odoratus, and of Erythrina corallodendron.

Cells differ in form according to the mode in which they are aggregated. They are frequently rounded or spherical, at other times they present angular or elongated forms, such as pentagonal or five-angled, hexagonal or six-angled, prismatic, square, fusiform or spindle-like. When the cells are so placed as to touch each other on every side, the Parenchyma is called complete. This is seen in the dodecahedral or twelve-sided (Fig. 2), and prismatic Parenchyma of pith, and in the flat tabular Parenchyma of the outer corky bark of trees. When the individual cells touch each other only at certain points, the Parenchyma is incomplete. This occurs in the case of the spherical and elliptical cells (merenchyma, μηρύειν, to revolve) of succulent plants, such as the Cactus, and in the stellate or star-like cells (actinenchyma, ἀκτιν, a ray) of the Rush, Callitriche verna, and Bean (Fig 10). In incomplete Parenchyma spaces are left between the cells, which are either large circumscribed cavities called Lacuna, or continuous passages called Intercellular Canals. The spaces between the cells are filled either with fluids of different kinds, or with air. Occasionally the intercellular

productive cells called spores are met with, having thread-

¹ See figure and description in Balfour's Class-Book of Botany, p. 1072.

For the use and construction of the microscope, see article Microscope. See also Quekett on the Microscope. Balfour's Class-Book of Botany. Bennett's Lectures on Clinical Medicins. Schach; on the Microscope.

Fig. 10.

Stellate or star-like cellular tissue of the Bean, with in-tercilular spaces

or Lacunæ.

Botany, substance assumes a thickened or corky consistence, and unites the cells firmly; and it appears to be sometimes prolonged over the surface of the plant in the form of a cuticular covering.

2. Physiology of Cells.

When we consider that cells are of universal occurrence in the Vegetable Kingdom, and that they constitute, in some instances, the entire structure of plants, we can easily understand their importance in a physiolo-

gical point of view. They are capable of carrying on all the functions of plant-life. The life of an individual cell may represent that of the entire plant. In the case of a unicellu-

lar Alga, as Palmella (Fig. 11), we meet with a simple cell which absorbs nutriment from the atmosphere and the soil, and forms certain organizable matters, some of which are employed in building up its texture, while others are secreted or set apart for ulterior purposes in its economy. Those actions are frequently accompanied by an evident movement of fluids and granules. In the progress of time cellules are developed in the interior of the cell, which are discharged as

Fig. 11.
Unicellular Alga
(Palmella cruento).
The cell, a, absorbs, secretes, and forms new cells by a process of fissparous division, first into two, b b, and then into four parts, c. independent cell-plants capable of performing all the function of the parent cell. In other instances, the original cell gives origin to the new cells, either by means of nuclei (Fig. 12), or by a constant process of division (Fig. 13), until at

length a cellular plant is produced consisting of numerous cells variously arranged. In higher plants, cells undergo transformations

orma-Fig. 12. Fig. 12. Fig. 13. Fig. 13. fitting Fig. 12. Cells containing nuclei or cytolasts, from which new cells are produced by intra-cellular cyto-

them for their special functions. Vital operations are carried on in all plants by means of cells, the

constitution and functions of which vary according to the nature of the plants and the position in the scale of organization which they occupy. In the higher classes of plants, certain cells are concerned in the secretion of organizable products, which are elaborated by others into new tissues. The life of plants consists in the regular action of different kinds of cells, which are concerned in the formation of new organs and of new products. In cells there are observed the absorption and movements of fluids, the elaboration of these by exposure to air and light, and the formation of new cells.

In its early state a plant consists of one or more cells. These appear to be produced from a viscid substance of an albuminous nature, to which the names of Protoplasm, Cytoblastema, and Vegetable Mucus have been given. This substance is first homogeneous, then granular; and according to some exhibits minute fibres. It is coagulated by alcohol, and coloured yellowish-brown by iodine. It is considered as the earliest stage of vegetable tissue, and as being endowed with a certain formative power. By Barry, the organizing matter is called Hyaline (ναλος, glass), from its pellucid nature. Some say that in this protoplasm nuclei are developed which give origin to cells; others state that the nitrogenous matter becomes at once divided into celllike cavities, each of which produces a covering of cellulose for itself. The formation of nuclei or cells in a protoplasmic matrix, without the influence of another cell previously existing, may be called extra-cellular.

When a cell has been produced, we can then trace some Botany. of the stages by which new cells are formed. This process is called cell-development or Cytogenesis (κύτος, a cell, and γένεσις, origin), and it has engaged the attention of many able physiologists. There appear to be four modes in which vegetable cells are multiplied, viz., by nuclei, by division, by gemmation, and by conjugation. New cells originate in the protoplasmic fluid contained in a parent cell by a process of *intra-cellular* formation. The new cells may either proceed from a nucleus, or, as Schleiden calls it, Cytoblast (βλαστός, a germ); or they may be formed at once in the protoplasm. In the former case, the nucleus becomes as it were the centre of vital action, and on one side of it a bladder-like vesicle arises (Fig. 14, b). This original

vesicle is bounded by a protoplasmic membrane, which ultimately becomes covered with a deposit of cellulose. The protoplasmic membrane forms the inner lining (primordial utricle of Mohl) of the new cell, and to it all the subsequent vital actions of the cell are referred. The nucleus either remains in the cell-wall, or it is absorbed. The newly-formed cell contains a formative fluid in which nuclei are produced, which, in their turn, give origin to other cells. Besides a nucleus, there are seen occasionally in cells very minute bodies called nu-

cleoli, which some consider as being concerned in forming the wall of the nucleus. The nuclear formation of cells has been fully illustrated by Schleiden in the case of the Embryo plant. According to Mohl the nucleus is in the centre of the cell, and is attached to its walls by filamentous processes of protoplasm, as seen in the hairs of Tradescantia. When no nucleus is present, the protoplasm at once forms cells. This is called non-nuclear or free cell-formation. In both instances the formation of new cells takes places in the interior of previously formed cells. In progress of increase, nucleated and non-nucleated cells cause absorption of the walls of the parent cell, which finally disappears. It sometimes happens that the nucleus itself divides into two by a contraction in the middle, and each of its parts gives origin to cells. In this way a rapid multiplication of cells takes place. In Figure 14, b, there is represented a parent or

mother cell, containing two nucleated cells in its interior. These gradually increase, cause absorption of the walls of the parent cell, and become free. In Figure 14, a, a parent cell is shown enclosing five nucleated cells.

After a cell is formed, we often remark that its contents divide into two or four parts. This is accomplished by the folding inwards of the protoplasmic inner lining, the primordial utricle of Mohl. Each division forms for itself a covering of cellulose. These newly-formed cells increase, cause absorption of the walls of the parent or mother cell, and separate from it Portion of a cell plant as distinct cellular formations capable of going through the same process of division. Sometimes a cell divides into two or more parts, each of which becomes a separate cell, without any destruction of the walls of the original one, as shown in Figure 15. This is accomplished by a similar folding of the inner lining, and a subsequent formation of cellulose in each division,

ortion of a cellniar plant
(Conferva glomerata), showing at a the primordial utricle
or inner cellwall folding
inwards, so as
to make a septum or partition, which is
represented at
b in a com-

but it differs from the previous method of division in the circumstance that the walls of the parent cell remain without being absorbed. These modes of cell-multiplication are called fissiparous, or merismatic (fissum, cleft, μερισμός, division)

Cells are also produced by a process of budding; in other words, by a continuous growth from various parts of preBotany.

viously formed cells. A cellular protuberance or mammilla appears either at the apex or at the sides of these cells, which elongates and ultimately divides by a partition or septum into two, one of which is arrested in its development, and the other goes on elongating and dividing. In this way a continuous row of cells is produced, as in certain Algæ and in the Yeast plant (Fig. 16), or a branching filament, as in some kinds of Confervæ (Fig. 17), and moniliform Fungi (Fig. 18), or a flattened thallus composed of interlacing cells,

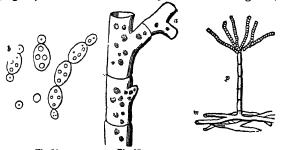

Fig. 16. Fig. 17. Fig. 18.

as in Lichens. This mode of cell-multiplication is gemminations, and is said to take place by a process of gemmation.

parous, and is said to take place by a process of gemmation.

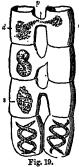

Another mode in which new cells are formed is by the conjugation or union of two cells having different contents

(Fig. 19). This is well seen in Zygnema. and other allied plants, and it will be particularly noticed under Embryogeny. This process may be called generative cell-production. The cell developed in this way constitutes the spore or germ in the lower class of plants, and the first cell of the embryo in the higher plants. The embryonic cell produces nuclei, by means of which a multiplication of cells is effected.

The rapidity with which cells are developed in some cellular plants is astonishing. Ward observed Phallus impudicus shoot up three inches in the space of twenty-five minutes. Bovista gigan-teum (gigantic puffball) has grown in a 'Alga (Zygnema), unti-single night in damp weather from the size of a mere point to that of an enormous gourd. From an approximate calculation, it is found that in this plant

not less than 20,000 new cells were formed everyminute. Kieser calculated that the tissue of some Fungi augmented at the rate of 60,000 cells per minute. Large tracts of snow in the arctic regions and in alpine districts are sometimes suddenly reddened by the development of innumerable cells of the Red Snow-plant.

Cellular tissue is very hygroscopic. If cellular plants, such as Sea-weeds, are dried, and then put into water, they take up the fluid rapidly. Some of them, as the different species of Tangle (Laminaria), have been used as hygrometers. In mosses, the cellular teeth of the peristome (Fig. 20, p), curve inwards on the application of moisture, by the distension of the teeth of the application of moisture, by the distension of the outer row of cells. The twisting of the stalk of Mosses, and of the awn of the wild Oat, are accounted for in a similar manner.

anow the contents of one cell, c, to pass into another, d, and thus give origin to new cells, s, which receive the name of spores.

peristome, a, which fold in-wards when moisture is ap-plied.

The fronds of a species of Lycopodium (L. squamatum or Botany. Selaginella convoluta), from Brazil, curl inwards in the dry season, so that the plant appears like a brown ball, and during the wet season they spread out so as to cover the soil. The plant called Rose of Jericho (Anastatica hierochuntina), shows a similar hygroscopicity in its pod; and some of the Cape species of Mesembryanthemum open their seed vessels when moisture is applied. The spores or germs of Horsetails (Equisetum) are provided with cellular clavate filaments (Fig. 9), which contract and expand under the influence of moisture and dryness, and thus assist in placing the germ properly in the soil. These Equisetum spores are interesting objects under the microscope, and their movements are seen by breathing upon them. Hairs, which are composed of cells,

also show hygroscopic properties.

Liquids pass through the walls of cells by a process of imbibition. Thin-walled cells take up fluids very rapidly. To the movement of fluids through membranes of different kinds Dutrochet has given the names of Endosmose (ἔνδον, inwards, and ωσμός, impulsion), or inward movement, and Exosmose (ἔξω, outwards), or outward movement. These movements take place both in living and in dead tissue, and they are influenced by the nature of the fluids and of the membrane. The fluids on either side of the membrane must differ from each other in density, and they must have an affinity for the interposed membrane, and for each other. By the endosmotic process, a thin liquid passes in large quantity and with great force through a vegetable or animal membrane, in order to mix with a denser liquid, while the latter passes outwards in small quantity by a slower exosmotic movement. If a unicellular plant, as one of the cells of the Yeast plant, is placed in a dense liquid, the contents of the cell pass cutwards rapidly, and the cell becomes more or less collapsed; if, on the other hand, it is put into a thin liquid, the reverse takes place, so that the cell is distended.

The cells of plants contain liquids of different densities, and hence these movements must be constantly taking place, so as to cause an interchange of their contents. The bursting of the seed-vessel of the Elaterium (Ecbalium purgans), and of the Balsam (Impatiens), is traced in part to the distension of cells by endosmose, which causes a curvation in the parts and an ultimate rupture. It must, however, be borne in mind, that endosmose is modified in the living plant by the vital actions going on in the cells, and that it is to these actions we must refer the continued movements of fluids through the cell-walls.

The endosmotic phenomena may be illustrated by means of a tube of glass, containing syrup or a saturated solution of salt, the end of which is covered by a membrane, such as a piece of bladder, and then placed in water. In this case the water will enter in such quantity into the interior of the tube, through the membrane, that the fluid will rise. With a membrane about 1-6 inch in diameter, a tube of about 1-12th of an inch, and syrup of density 1.083, the fluid rose, according to Dutrochet, more than an inch and a half in an hour and a half; when the syrup had a density of 1.145, the fluid rose nearly three inches; and when the density was 1 228, the rise was four inches. The force with which the movement takes place is very great. Dutrochet estimated that in the case of syrup of density 1.3, the force of endosmose was equal to the pressure of $4\frac{1}{2}$ atmospheres.

In many cells there is observed a distinct motion of fluids and granules. Schleiden thinks that this takes place in all active formative cells at a certain stage of growth. Mohl looks upon it as a universal phenomenon, and says that it is connected with the protoplasm, and not with the watery cell-sap. This intra-cellular movement or circulation is seen in many aquatic plants as well as in certain hairs. It has received the names of Rotation and Gyration. It is confined to individual cells, and its direction is more

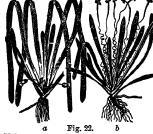

Botany. or less spiral. In Characeæ (Fig. 21) this spiral intra-cellular movement is observed easily under a moderate microscopic power. During the healthy state of the plant, a constant motion of fluid containing granules takes place, the current passing obliquely up one side, changing its direction at the extremity, and flowing down the other side. The stream takes a spiral course, and the ascending and descending currents are bounded by transparent spaces which appear to be caused by the adhesion of an internal membranous sac to the outer envelope. The space between the outer and inner wall is thus divided into two cavities, which communicate with each other at the ends of the cell. The fluid does not pass from one cell to another, and if one of the long cells is divided by a ligature, a separate movement is seen in each division. Rotation continues for some days in detached cells placed in water.

Fig. 21.

A small portion of a Chara magnified to show the magnified to show the certification. The arrows mark the direction of the fluid and granules in the different cells. The clear spaces are parts where there is no movement. of the cell. The fluid does not pass

In the cells of Vallisneria spiralis (Fig. 22), a diœcious

aquatic found in ditches in the south of Europe, an intra-cellular movement takes place, and is easily seen under the microscope by laying a portion of the leaf in water, and making a slanting section of the end of it, so as to render the object more transparent by transmitted light. If the movement is not visible, the leaf may be vallisneria spiralis, an aquatic plant immersed for a short time in water of the temperature of 70° or 80.° The piece of The piece o the leaf should always be prepared for an hour before it is

exhibited. In the cells there are numerous green chlorophyll grains, some starch granules, and an occasional large nucleus, which are carried with a mucilaginous fluid round the interior of the walls of each cell, as represented in Fig. 23. This movement is seen not only in the cells of the leaf, but also in those of the root, flower-stalk, spathe, and calyx. The movement takes different directions in different cells, but it seems to keep the same course ; in any given cell; for if stopped, it resumes the same direction. The motion continues for many days in a detached piece of the leaf when kept in water. The rapidity of the movement varies from half an inch to five inches per hour.

In Vallisneria the motion ceases entirely at about 45° Fahr., while in Chara it goes on at a lower temperature. A moderate heat quickens the circulation, but if above 150° the motion ceases. It is said to go on even in darkness, and the presence of green granules does not appear to be necessary, for it is seen in the Large internal ransparent roots of Vallisneria. Prussic acid, solutions of opium, of acetate of lead, and of corrosive sublimate, alcohol, acids, and alkalies, cause cessation of the movements. Similies, cause cessation of the movements. Similar motions are seen in many other aquatics, more espe-

cially in the cells of Anacharis Alsinastrum, a plant which Botany. seems to have been introduced into Britain from America, and is now naturalized.

The cause of these intra-cellular motions is obscure. They appear to be connected with the nourishment of the cell and the process of cytogenesis. Some have attempted to account for them by physical causes, but the explanations given are very unsatisfactory. Certain authors have referred the phenomenon to endosmose depending on different densities in the cell contents, while electrical agency has been called into requisition by others. Amici thinks that in Chara the rows of chlorophyll-granules which line the walls of the cells exercise a galvanicaction upon the sap, and thus give rise to the motion. The action of the nucleus has also been thought to account for the phenomenon. It is not connected with the general circulation of the sap, but is a special movement in individual cells. yet no good explanation has been brought forward, and all we can say is, that the movements are of a physico-vital nature.

Some cells connected with the lower tribes of plants move about in a liquid medium. Species of Oscillatoria have an undulating movement, and when placed in water in the field of the microscope, they seem to pass from one side to the other. Their elongated filamentous cells sometimes twist, and then project themselves forward by uncoiling. Oscillating movements are also seen in species of Pleurosigma and other Diatoms. In many Algals the cellular spores are surrounded by vibratile hairs called cilia (Fig. 8), which continue to move for some time in fluid after the spore (zoospore) has been discharged from the plant. The ciliary motions cease when the spore begins to sprout.

III.--VESSELS AND VASCULAR TISSUE.

1. Anatomy of Vessels.

The vessels of plants which collectively form vascular tissue or Angienchyma (ἄγγος, a vessel) may be considered as differing from cells chiefly in their length. They are closed tubes tapering to each extremity. Their walls are composed of the chemical matter called cellulose in a membranous form, and they are thickened and altered in various ways by the formation of deposits in their interior.

Woody Tissue.—This is composed of thickened tubes or elongated cells, with conical extremities overlapping each

other, as seen in Figure 24. The tubes are said to be fusiform or spindle-shaped, and the tissue has received the name of Pleurenchyma, from a Greek word $\pi\lambda \epsilon \nu \rho a$, meaning a rib, on account of the support which it furnishes to the stems and leaves of plants. The woody portion of trees and shrubs, and of all the ordinary flowering plants, consists in part of this tissue. It exists also in the inner bark, and in the veins of the leaves. The materials used for ropes and cordage, linen, certain Indian muslins, mummy cloth, and mats, consist of the woody fibre of plants from which the more delicate tissues have been removed by maceration in water. Flax or lint is thus procured from the bark of Linum usitatissimum,* hemp from Cannabis sativa, New Zealand flax from Phormium tenax, Pita flax from Agave americana, Sun-hemp from Hibiscus cannabinus, and bass or bast from the common Lime or Linden-tree. Fibres are also procured for manufacture from the Pine-apple plant (Ananassa sativa), from Yucca gloriosa, from Boehmeria nivea, which yields the Chinese grass fibre, from most of the plants belonging to the mallow and nettle tribes, and from some of the leguminous plants, such as Crotalaria juncea which supplies a kind of Bengal hemp. If the maceration of the fibre is carried to a great ex-

tent, a pulp is formed from which paper is manufactured.

Botany.

Pleurenchyma does not occur in cellular plants, such as Lichens, Sea-weeds, and Mushrooms. The tissues of these plants speedily disappear under the action of water, and hence, perhaps, the reason of their rarity in a fossil state. In the very young state woody tubes are delicate, and it is only in proportion as they attain maturity that their walls acquire a thick consistence. This depends on the formation of layers of cellulose, which have received the name of ligneous matter. In the sap-wood of ordinary trees the woody tubes are thickened in their walls, but are pervious; while in the heart-wood they are rendered solid by the deposited matter, which is often variously coloured. Some of the fully-formed woody tubes, when cut across, exhibit distinct zones or circles of ligneous deposit. The diameter of the

woody tubes varies from 2000 th to 200 th of an inch.

Punctated or Disc-bearing Woody Tissue.—This kind of woody fibre or pleurenchyma is seen in firs and other conebearing trees. It is sometimes called glandular woody tissue. When a section is made in the direction of the rays running from the centre to the circumference of the stem, the fibres exhibit under the microscope discs or large circular dots, which are saucer-like spaces or depressions on the walls of the tubes. They are seen in Fig. 25. When

two woody tubes lie together face to face, the depressions or hollowed-out spaces on each of them are applied like two watch-glasses leaving lenticular cavities, which are sometimes filled with air. When viewed by transmitted light under the microscope, these appear like circular discs. The dot seen in the centre of the disc depends on a portion of the wall being thinner than the rest. In Fig. 26 this structure is seen

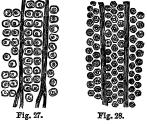

in a magnified form. Fig. 26. Punotated woody tissue of the fir. The walls of the marked pf, the internal cavity of the fibre c f, and the lenticular cavities c l.

These earlies appear as discovery consisting of cellular tissue proceeding from the centre to the circumforence.

formed between the two contiguous fibres, r m being one of the cellular rays proceeding from the centre to the cir-

cumference, interposed between the walls of two contiguous fibres. In the case @@ of some fossil woods, pieces of silica like double-convex lenses have been removed from the cavities. The discs are in single, double, or triple rows (Figs. 27, 28). When there is more than one row, the individual discs in the rows are either at the same level, that is, opposite to each other (Fig. 27), as in

the case of ordinary pines; or they are at different levels, that is, alternate with each other (Fig. 28), as in Araucaria. Sometimes spiral fibres are seen between the discs. Woody

tissue with discs, but without the central dot, occurs in many Botany. plants, as in Drimys Winteri,* and Illicium floridanum.

Dotted or Pitted Vascular Tissue.—The vessels, or, as *Pl. CXI. they are often called, Ducts, forming this tissue, are usually continuous tubes of a larger size than the other vessels of plants (Fig. 3), and presenting often broad or oblique extremities in place of pointed ones like other vessels. Their dotted or pitted appearance depends on the mode in which the encrusting matter or cellulose is formed inside. This matter in place of being deposited equally over the whole surface of the membrane, as in ordinary woody fibre, leaves rounded uncovered spots at various intervals; and these, when viewed by transmitted light, appear from their thinness to be perforations or holes. Hence the name Porous, which is often applied to these vessels. In old dotted ducts it is occasionally found that the thin membrane of the dots or pits has been absorbed, and actual perforations have taken place. Dotted vessels frequently exhibit contractions at intervals, giving rise to a jointed or bead-like appearance.

In such cases, as in Figure 29, they are seen to be formed of dotted cells placed end to end, with the partitions between them obliterated, so as to form continuous cylindrical and sometimes branched tubes. Occasionally they seem to be formed, as in Rhubarb, by a filling up of the interspaces between fibres, until a small pit only remains; or, as in Alnus serrulata, by a number of lines arranged at first like those of a ladder, and then united by transverse ones forming a grating, the angles being finally filled up and rounded; or, as in Populus tremuloides, by a uniform deposit over the whole membrane. In the Elm and Lime the dotted ducts have sometimes spiral fibres ramifying between the dots. The membranous walls of dotted vessels occasionally unrol in a spiral manner. Dotted ducts are found in the wood of trees, and they constitute the large rounded

openings which are seen in the transverse section of the stems of Oak, Poplar, Willow, &c. They also abound in the Bamboo (Fig. 4), and in other plants of rapid growth. The names of Bothrenchyma and Taphrenchyma, given to this tissue, are derived from Greek words βόθρος and τάφρος, signifying a pit.

Spiral vessels.—These form the tissue called Trachenchyma (τραχύς, rough) on account of its resemblance to the tracheæ or air-tubes of animals. They are tubes tapering

to each extremity, and having their membranous walls strengthened by the formation of elastic spiral fibres within (Fig. 30). They vary from 3000th to 300th of an inch in diameter. When lying together the vessels overlap each other at their extremities, and occasionally, by the absorption of the membrane, perforations of their walls take place, so as to establish a communication between two contiguous tubes. fibres are usually rounded and simple; but sometimes two or more are combined so as to form a flat band. These flat ribands, consisting of fibres which vary in number from 2 to 25, or more, are met with frequently in the stems of Bananas and Plantains, and in the shoots of Asparagus. The spirals in such cases are called compound, and the vessels Pleiotracheæ (πλείων, more). The spiral fibres have such tenacity, that when the vessels are ruptured they can be pulled out and separated from the inside of the membrane. This capability of being unrolled characterizes the fibre of true spiral vessels. On breaking the young shoots or leaf-stalks of the Geranium, Strawberry, and Rose, or the leaves of the Hyacinth, Amaryllis, and Banana, and pulling the parts gently asunder, the fibres can

Fig. 30. Spiral vessels sels over lapping at their point-

Botany. be easily seen in the form of a fine cobweb. When the aerial stems of the Banana and Plantain are cut across, the spiral fibres may be pulled out in large quantity so as to be used for tinder.

The coils or volutions of the fibre are said to be in general left-handed, that is, turning to the left of a person supposed to be in the axis. In the garden lettuce vessels are met with, some having the fibre turning to the left, others to the right. In the scarlet bean the coils of the fibres are left-handed, while the plant itself turns to the right in twining. Spiral vessels are abundant in young plants and shoots, while in the hard

stems of trees and shrubs they chiefly surround the pith.

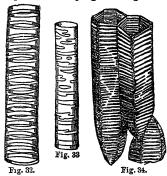

Modifications of Spiral Vessels.—The spiral vessel is the type of what is called the Fibro-vascular tissue, or that tissue which is composed of vessels having membranous walls strengthened by fibres of some sort. In their perfect condition the vessels have a complete spiral or cork-screwlike coil inside, which is elastic, and can be unrolled. In different plants, however, and in different parts of the same plant, the spiral vessel undergoes certain modifications and changes. Sometimes, as in ferns, the spiral fibres become united to the membrane so that it cannot be unrolled. This constitutes what is called the *Closed* spiral. At other times the fibre is broken up into rings, reticulations, bars, or dots. These changes take place in the progress of growth, (Fig. 31) and

their various stages may be traced in the vessels of such plants as the garden balsam or melon. Annular (annulus, aring) vessels are those in which the fibre is in the form of rings (Fig. 32). These rings in Mammillaria quadrispina, and in some other plants of the Cactus tribe, are very deep, and leave only a small hole

Fig. 31. Fig. 32. Fig. 32. Fig. 33. Vessel partly spiral and partly annular taken from the melon plant.

32. An annular vessel taken from the melon plant. The dots are in this case opaquo, and thus differ from pits in porous vessels.

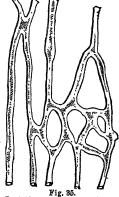

34. Scalariform or ladder-like prismatic vessels of tree ferns.

in the centre of the vessel. Annular vessels are from 800 th

to $\frac{1}{\sqrt{100}}$ th of an inch in diameter. Reticulated (reticulum, a net) vessels (Fig. 33) have interlacing fibres on the membrane, while in Scalariform (scala, a ladder) vessels (Fig. 34) the fibre is so broken up as to appear in the form of bars or lines like the steps of a ladder, whence their name. The entire walls of some scalariform vessels are capable of being unrolled in a spiral manner. In Ferns we meet with scalariform vessels which assume a prismatic form. In place of lines, the fibre is in some instances so broken up as to appear in the form of dots or opaque points. The ap-

F1g. 31.

pearance of bars, dots, and reticula-tions, may sometimes be traced not Laticiferous vessels or Cinen-chyma from the dandelion.

to a thickening of the membrane by means of fibres, but to an actual thinning of the membrane, such as has been already noticed in the case of dotted ducts.

Laticiferous Vessels.—These vessels (Fig. 35) consist of long branching tubes or passages, having a diameter of about 1400th of an inch, forming, by their union, an anastomosis or net-work, like the veins of animals. They receive their name from containing a fluid called Latex, of a granular nature,

often milky or coloured, and well seen in the India Rubber and Botany. Gutta Percha plants, the Mudar plant, the Cow-tree, Spurges, Dandelion, Lettuce, * Chicory, and Celandine. It frequently *PICXXIII contains a large quantity of caoutchouc. The Latex exhibits movements which have given origin to the name Cinenchyma (κινέειν, to move), applied to Laticiferous vessels by some authors. When fully formed, the vessels of latex exhibit in their course contractions and dilatations of an irregular kind. They are considered by some as composed of cells placed end to end, with their partitions more or less completely absorbed; while others look upon them as inter-cellular canals lined with a special membrane. These vessels are found especially in the bark and leaves of plants. The milky sap of Euphorbia phosphorea, according to Martius, is luminous.

2. Physiology of Vessels.

We have seen that the plant, in its earliest stage of development, consists entirely of cells. It is from them, accordingly, that the other structures are formed. Some cells become elongated, so as to form fusiform tubes, the walls of which are thickened and strengthened by deposits of different kinds, and thus give rise to woody tubes, dotted vessels, and fibrovascular tissue. In connection with these vessels are observed nucleated cambium cells, which appear to be concerned in their development. Barry maintains that in every instance in which fibres are present in tissues, he has noticed filaments of a similar nature in the earliest state. Agardh has recently stated that fibres are the origin of the tissues, and that the cell-walls are made up of bundles of solid fibres interwoven together. The tubes forming the wood (Fig. 24) are pervious to fluids in their young state, but their walls soon become thickened by deposits of lignin, and in the heartwood of trees their cavities are obliterated. This filling up of the tube takes place often in a concentric manner, and when it is completed the active life of the cell or tube may be considered as having terminated. The dotted or porous vessels (Fig. 3) constituting bothrenchyma, do not exist in all vascular plants. Thus they do not usually exist in Conifers. These vessels appear to be employed in the rapid transmission of fluids, and they are so constructed as to unite the utmost possible strength with the greatest lightness.

The functions of the fibro-vascular tissue (Figs. 30-34) have been long a subject of dispute. Early authors, such as Grew and Malpighi, considered them as tubes for the transmission of air, probably from their resemblance to air-tubes of animals. Hales mentions that air-bubbles arose from the vessels of the Vine when cut, and Bischoff, in his Dissertation on the Functions of the Spiral Vessels, says that he distinctly observed air to come from the spirals of Cucurbita Pepo when the stem was cut across with a very sharp knife, as well as when the vascular bundles were placed under water and gently pressed. During the day the air was found to contain 279 to 298 per cent. of oxygen. When the cut stem was inserted in coloured solutions, he found that the fluid in these circumstances entered the spiral vessels as well as the other tissues. The recent experiments of Hoffmann confirm in a great measure these observations. He found that in Monocotyledons and Ferns, spiral vessels, and those allied to them, such as annular and scalariform vessels, usually contained air in their normal condition; but if there was a rapid and copious entrance of sap, then the fibro-vascular tissue took up liquids as well as air. When the roots were cut across and immersed in water, then the liquid passed into all the tissues, including the spirals. From all the observations made, it would appear that spiral vessels and their allies are receptacles for gaseous matter formed in the course of the movement of the sap.

Laticiferous vessels (Fig. 35) are distinguished from others by their branching and anastomosis. Most authors believe that they contain the elaborated sap which has been exposed to the influence of air and light. The fluid contained in these

Botany. vessels is sometimes clear and transparent; at other times opaque, from the presence of granules of resin, caoutchouc, and other matters. In plants with milky and coloured latex, as the India Rubber plant (Urostigma elasticum), the Gutta Percha tree, Dandelion, Euphorbia, and Celandine, when examined under the microscope, evident movements have been perceived in the laticiferous vessels. In making this examination, it is necessary to fix upon a more or less transparent organ, and to examine it while still attached to the plant, so as to avoid all sources of fallacy. In the calyx of Celandine (Chelidonium majus) the orange-coloured fluid contained in the laticiferous vessels can be distinctly seen moving with great rapidity, so as to resemble in many respects the appearance presented by the circulation in the web of a frog's foot. In the stipule of the India Rubber plant, a similar motion, but usually slower and less apparent, may be detected without injuring the plant. These movements were noticed by Schultz, and were called by him vital. Mohl and others have recently attempted to show that the movements are merely caused by injury done to the tissues in submitting them to microscopic examination. But this will not account for those cases where the motion of the latex was seen in an organ without detaching it from the plant. Moreover, it is by no means difficult to distinguish between the continuous rhythmical motion in these vessels and that caused by pressure or by injury. When the stipule of Ficus, still attached to the plant, is laid gently on a glass plate under the microscope, we may, by applying artificial pressure, show that the oscillation thus caused is different from the circulation in the vessels. The movement in the laticiferous vessels has received the name of Cyclosis (κύκλωσις,

motion in a circle). It seems to take place in all directions, the currents, as shown in Fig. 36, running in contrary directions in contiguous vessels. The movement is said to be most vigorous in parts which are in the progress of development. It is promoted by the application of heat, and it is checked by cold and by an electric shock. Carpenter considers it as analogous to the capillary circulation in animals. It is not caused by a vis a tergo, because it is by no means constant in its direction, and there is no organ to supply a propelling force; and it cannot be attributed to a vis a fronte, like that which operates in causing the sap to ascend from the roots to the leaves. Moreover, it goes on for some time in parts detached from the rest, where

Fig. 36.
Branching and anastomosing tubes of laticiferous vessels. The arrows mark the direction of the current.

neither of these powers can be exerted. There is no evidence of contraction in the vessels themselves to account for the phenomenon. It seems to be a peculiar vital movement connected with formative actions, and attributable to affinities existing between the tissues and the fluids concerned in nutrition.

IV .- CONTENTS OF THE ELEMENTARY TISSUES.

It is not proposed at this place to give an account of all the substances which are found in the tissues of plants, but simply to notice a few of the more evident contents of cells and vessels. Some substances are found generally in the cells and vessels of all plants, while others are very limited in their distribution. To the former class belong cellulose, lignin, starch, gum, sugar, oils, colouring matter, and certain nitrogenous and saline compounds; to the latter belong alkaloids and some special secretions.

Cellulose.—This is an essential part of the structure of cells and vessels. It is in many respects allied to starch, and is changed into starch by the unaided action of heat, or by sulphuric acid, or caustic potash When iodine is applied

to it, it becomes yellow, and if sulphuric acid is added, a blue Botany. colour, like that of iodide of starch, is produced. Cellulose was long considered as peculiar to vegetable tissues, but it has been recently detected by Schmidt, Löwig, and Kölliker, in the tunics of ascidia and other molluscous animals. The thickening of the cellular membrane is accomplished by the deposition of layers of encrusting matter, to which the name of Sclerogen (σκληρὸς, hard) or Lignin has been given. This substance may be looked upon as a modification of cellulose. It is frequently seen in the form of distinct concentric layers, which vary in their composition in different circumstances. The hard cells in the stone of the peach, and in the shells of other fruits and seeds, consist of cellulose, with deposits of lignin. So also woody fibre, the encrusting matter of which varies in hardness and colour in different trees and shrubs. The spiral threads, rings, and bars, in the membrane of cells and vessels, consist apparently of two layers, one being cellulose, the other woody matter. Cork is a nitrogenous substance, which, next to cellulose, according to Mitscherlich, is the most important constituent of the cell-wall. It occurs in a marked degree in the outer bark-cells of many trees, and it is also found in other plants, such as in potatoes. In the latter the cork-cells do not contain starch, and they are thus distinguished, as well as by chemical properties, from the cells made up of cellulose. Cellulose, corky substance, and fatty matters, seem to be found in the same cell; and when the cellulose has been absorbed, the corky substance alone remains. It forms the outermost part of the cell-wall, and unites the cells together.

Starch—Is one of the substances found in great abundance in the cells of plants, where it is stored for the purposes of nutrition. It is composed chemically of Carbon and the elements of water (Hydrogen and Oxygen), its formula being C_{12} H_{10} O_{10} . It is not found in animal tissues, although a substance isomeric with it is stated to have been detected in them by Gottlieb. A distinguishing character of starch is the blue colour which it assumes on the addition of iodine. It occurs in fine grains, more or less oval or rounded, which vary in diameter from the 4000th to the 240th of an inch. The individual grains either lie distinct from each other in the cells, as in the potato, wheat, and

peas (Fig. 37), or they are aggregated so as to form compound grains, as in West Indian Arrow-root, and Portland Sago procured from Arum maculatum.* Grains of starch frequently present at one end a spot called the hilum, which is seen in the grains given in Fig. 37. It is a concavity or nucleus over which successive layers have been deposited, giving rise to the striated appearance seen in potato starch. Starch is accumulated in the internal, and often in the subterranean parts of plants. It occurs abundantly in fleshy roots, and in stems, as well as in seeds and fruits, and is easily separated by washing. The ordinary cultivated

Fig. 37.

grains yield starch in considerable quantity, so also do the Potato, Arrow-root and Cassava plants,* the Sago-palms, and *Pl. CXIII. Banana fruit. That procured from the Arrow-root plant Fig. 1. (Maranta arundinacea) consists of dull white grains, while that from the potato, and from various species of Canna supplying tous-les-mois, is in the form of large shining particles. Sago and Tapioca are granulated forms of starch, the former being procured from the cells of various species of Sagus and Metroxylon, the latter from the Cassava plant. The existence of starch in the bark and young wood of trees, such as the Birch and Pine, renders them useful as articles of food in cold countries. Lichenin is a form of starch existing in the cells of Iceland moss and other lichens; while Inuline is the starchy matter supplied by the roots of the Dahlia, Dandelion, and Elecampane. By the action of

* Plate

Botany. prolonged heat, as well as by the addition of diluted sulphuric acid, and of malt, starch is converted into a soluble gummy substance called dextrin. The same change we shall find occurs during germination or the sprouting of the seed.

Gum—Is another substance contained in vegetable tissues. When pure, it is clear, soluble in water, and also in dilute acids, but not soluble in alcohol or ether. It is one of the forms through which vegetable matter passes in being applied to the purposes of plant life. It exists largely in the vegetable juices. From the bark of many trees it is procured in the form of an exudation. Two well-marked kinds of gum are met with: Arabine, soluble in cold water, constituting the chief ingredient of gum-arabic, procured from various species of Acacia; and Cerasine, insoluble in cold water, and readily soluble in boiling water, constituting the gummy secretion obtained from the cherry and plum. A substance called Bassorin, or vegetable jelly, is found in Tragacanth, the roots of some Orchids, as well as in Carrageen (Sphærococcus crispus), and other sea-weeds. It is allied to gum, but differs in swelling up and becoming gelatinous when mixed with water. Another jelly-like substance called Pectic acid exists in the juice of turnip, beet, and carrot, as well as in the apple, pear, and other common fruits.

Sugar—Occurs abundantly in the sap of plants. When pure, and in a solid state, this substance is crystalline, and soluble in water. It occurs, however, in an uncrystallizable form. There are two marked varieties of it. Cane sugar, procured from the sugar-cane, sugar-maple, beet, carrot, and many other plants; and grape-sugar, occurring in numerous fruits, as grapes, gooseberries, currants, peaches, and apricots. The formula for Dry Grape-sugar is C12 H12 O12. During the sprouting of the seed, starch is converted into grape-sugar, and a similar change is induced by the action of malt, and of any ferment. A sweet substance (not a true sugar), called Mannite, is procured from the Manna-ash, as well as from various seaweeds, from species of Eucalyptus, and from the Dandelion.

The substances which have been noticed as occurring in the elementary tissues are important as organic products concerned in the growth and nourishment of plants. Some differences of opinion exist among chemists as to their exact atomic composition; it is sufficient at present to notice that they all consist of a definite proportion of carbon, united to oxygen and hydrogen, the elements of water. They are convertible into each other by the action of heat and of various chemical re-agents, and by the powers of vegetation. The ultimate composition of several of them is identical, and the difference of their properties, in such instances, seems to depend on differences in the arrangement of their atoms.

Another class of substances, found in the tissues of plants, and essential for the process of vegetation, consist of carbon and the elements of water, with the addition of nitrogen or azote. Hence they are called nitrogenous or azotized. They occur abundantly in the gluten of wheat flour. Schleiden includes them under the general name of vegetable mucus. The chief substances which enter into the composition of this nitrogenous matter are albumen, fibrine, caseine, legumine, and emulsine.

Nuclei.—The cells of plants, at some period of their existence, usually contain what are denominated nuclei or cytoblasts. The nucleus is a small rounded body resembling a minute cellule, which is either loose or attached to the walls of the cell containing it (Fig. 12). It frequently contains smaller bodies called nucleoli. The nucleus has an important function to perform in cell growth, as has been noticed under cytogenesis or cell-development, and after a certain period it frequently disappears.

Chlorophyll and Colouring Matters. - Chlorophyll or Phytochlor, is the matter which gives the green colour to plants. It is a coloured fatty or wax-like substance, which may be separated by the action of alcohol and ether. The green colour is associated with globules of various sizes,

which are either free or united together. The globules of Botany. chlorophyll can be seen under the microscope in any of the green parts of plants. In delicate structures, such as the cellular tissue of mosses and liverworts, they are easily examined. The colour is only produced under the action of light; hence chlorophyll exists in the superficial cells of the parenchyma, thus differing from starch, which is produced in the internal and subterranean organs, whence light is excluded. It undergoes changes according to its state of oxidation; hence the tints which the green leaves acquire in autumn. There would appear, therefore, to be a colourless chlorophyll present in plants, which is acted on by light, oxygen, and other agents, so as to give rise to green, yellow, and red tints. Schleiden says, the yellow leaves in autumn contain proportionately more wax than the green leaves of summer, the yellow rind of the ripe fruits more than the green rind of unripe fruits. The tints of flowers depend either on variously-coloured insoluble globules, which are considered to be of a nitrogenous nature, or on soluble substances which have not been fully examined. Colouring matters not green are included under the name of Chromule.

Oily, Fatty, and Resinous Matters. - These are contained in cells and in special canals and cavities, called receptacles of secretion. The oils are either fixed or volatile; the former being divided into drying, fatty, and solid; while the latter are distinguished according as they consist of carbon and hydrogen alone, or of these elements combined with oxygen or with sulphur. Resinous matter occurs either in the form of fluid balsams, or of the various kinds of solid resin and pitch. In the rind of the orange and lemon, receptacles of oil occur. These are represented in Fig. 38,

which is a vertical section of part of the rind & of the orange, the reservoirs of volatile oil being marked RRR. The cellular tissue of the rind is seen surrounding the oil

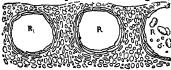

Fig. 38.

cavities, and the cells are elongated and condensed,

so as to form a compact tissue in the walls. Turpentine canals are met with in the bark of Pines; and Vittæ or oil-canals in the fruit of Umbelliferous plants,* such as the Coriander. In*Pl. CXXI the fleshy covering of the fruit of the Olive, there are nume-Figs. 2 & 3 rous oil-cells. The fruit of the Guinea-palm yields a solid oil called Palm oil. The dotted appearance of the leaves of the orange, myrtle, Eucalyptus, and St John's wort, depends on the presence of numerous cells or cavities containing essential oil.

As allied to these secretions, we may notice Caoutchouc, which is found in the milky juice of plants, especially those belonging to the Fig, Spurge, and Dogbane orders. The trees most prolific in this substance are, Siphonia Caoutchouc, Urceola elastica, and Urostigma elasticum. Gutta Perchais the concreted milky juice of the Taban plant (Isonandra Gutta). Wax is also found in the tissues of plants, and it frequently occurs as a secretion on the stems, as in the Wax Palm, and on the surface of fruits, as in the bloom or glaucous secretion of the plum and the candleberry myrtle.

Air-Cavities.— Cells and intercellular spaces containing air
are found in many aquatic and Fig. 39.

vessels also contain various mineral and organic acids, combined with alkaline substances. The most important of these acids and alkalies will be noticed when considering the chemistry of vegetation, and the products furnished by different natural orders. At present we shall consider the composition of certain crystalline matters found in cells, to which the name of the Raphides (papis, a needle), has been given. These are present in greater or less quantity in almost all plants. They consist of oxalic, phosphoric, malic, sulphuric, and carbonic acid, in combination with lime, and they exhibit various forms. Crystals of phosphate of lime occur usually in the form of acicular crystals, varying from $\frac{1}{1000}$ th to $\frac{1}{1000}$ th of an inch in length (Fig. 41, r); to these the name of needles or raphides was originally given. Cells with clusters of raphides may be seen attached to the divisions between the cells in the Banana. Crystals of oxalate of lime assume an octohedral form, and vary from 10th to 20th of an inch in length (Fig. 42). They are abundant

in the root of Turkey Rhubarb, to which they impart grittiness, and in Old-Man-Cactus they constitute 60 to 80 per cent. of the dried tissue. The Squill bulb, and the bulb of the onion, exhibit raphidian cells, which are easily separated during the decay of the plants. In a single cell of the Poke (Phytolacca decandra), twenty to thirty crystals may be seen.

Siliceous matter occurs in the walls and cells, and enters into

gether.

V .-- INTEGUMENTARY SYSTEM.

The general Integumentary covering of plants consists of cells variously aggregated, and may be considered in connection with the elementary tissues. It has been divided into two parts—the Proper Epidermis, and the Outer Pellicle or Cuticle. The epidermis is formed of one or more layers of colourless thick-walled cells cohering together, so as to constitute a firm membrane, which can be pulled off from the subjacent tissue. The colour of the epidermis in general depends on that of the parenchymatous cells below, from which it can be separated as a colourless layer. Occasionally, however, the epidermal cells contain colouring matter, as well as waxy, siliceous, and calcareous substances. In the case of Orchids, it is not uncommon to find spiral cells

in the epidermis covering their aerial roots. The epidermis Botany. covers all parts of plants exposed directly to the air except the stigma, which is formed of loose cells at the upper part of the pistil or central organ of the flower. The epidermis is sometimes much thickened, as in the Oleander and American Aloe, by being composed of numerous layers of cells, while at other times it is very thin. A delicate epidermis, called *Epithelium*, lines the internal cavities of certain organs, such as the ovary containing the young seeds. The boundaries of the epidermal cells frequently assume a waved or sinuous aspect (Fig. 44). The outer cuticle is a thin . layer covering the true epidermis, and apparently formed from the cells of the latter. It may be merely a changed condition of the walls of these cells, or a modification of

the inter-cellular substance which surrounds the cells. It forms the covering of hairs, as seen in Figure 43, which re-

Fig. 43.

Cuticle, or outer integument of the Cabbage (Brassica oleracea), showing the covering of the hairs, h, and the openings called stomata, s.

presents the cuticle of the cabbage with hairs, h, and it extends into certain openings in leaves called stomata (Fig. 43, s). In plants constantly under water, and in certain of the lower tribes, the cuticle is the only integumentary covering. The outer cuticle is considered by Mitscherlich as a corky substance, which prevents the penetration of moisture. The same substance, according to him, cements the cell-walls.

Epidermal Appendages.—These consist of openings to which the name of stomates is given, as well as of hairs, glands, and scales. They are not invariably present in the epidermis of all plants, and some of them, after having been developed, disappear in the progress of plant growth. Their presence and absence, as well as their form and structure, give rise to important botanical characters. A surface without hairs is called glabrous, while one having hairs is pilose. When the hairs are short and soft, the surface is pubescent; when long, distinct, and tolerably soft, hirsute; when long and stiff, hispid; when the hairs arise in tufts, the term bearded or stupose is applied. When they are entangled like cotton, and at the same time rather rigid, the term tomentose is given.

Stomata or Stomates.—These are orifices between the epidermal cells situated on the leaves and other green parts of plants exposed to the air, and communicating with intercellular spaces. They are sometimes called breathing-pores.

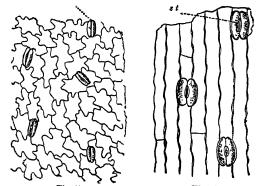

Fig. 44.

Fig. 45.

Fig. 45.

44. Epidermis of the garden Balsam (Balsamina hortensis), showing wavy lines bounding the flattened cells and stomata, st, of an elliptical form.

45. Epidermis of Lily, showing the lines bounding the compressed and elongated cells, and stomata, st, composed of two cells, with an opening or slit between them. Some granular matter is seen in the stomaticalls.

These openings are bounded by two (sometimes three or four) cells (Fig. 45, st), of a delicate nature, which have the

Botany. power of opening or closing the orifice. When moist, these cells become swollen, and, while they lengthen, curve outwards in the middle, so as to leave a free opening; when dry, they are shortened and straightened, and thus their sides are applied to each other, so as to close the orifice. They are not found in underground roots, nor in plants which have grown excluded from light; and they are rarely seen in those which are constantly under water. They are best seen on the under surface of leaves. When the epidermis becomes hard and glazed, stomata sometimes disappear, or are altered in their appearance. Their form is usually oval or elliptical, but in some instances they are spherical or quadrangular. They are either scattered singly at regular or irregular intervals over the epidermis, or they are arranged in clusters. Their number varies from 200 to 160,000 or more in a square inch of surface. In the leaves of the White Lily there are 60,000 in a square inch on the under surface, and about 3000 on the upper; on the leaves of the Cherry-Laurel there are 90,000 on the lower surface, and none on

Hairs—are prolongations of the epidermal cells. They consist either of single cells, more or less elongated (Fig. 46), or of several cells placed in a linear series, like beads, as in Figure 47, or united both longitudinally and laterally, as in Figure 48, where the lower part of the hair consists of numerous cells. In Figure 49, the hair divides at the apex into two, in a forked manner. In Figure 50, a, it splits into

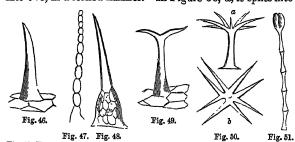

Fig. 48. Unicellular hair of the common Cabbage.

48. Sting (stimulus) of Nettle (Urtica dioica); its base is formed by numerous cells containing irritating fluid; from these arise a simple unncellular conical hair, which serves as a duct for conveying the fluid.
49. Forked or bifurcated unicellular hair of Draba or Whitlow-grass.
50. Unicellular hair a, of Alyssum, dividing into rays at the apex. The stellate or star-like arrangement is represented in the lower figure b.
51. Glandular multicellular, or many-celled hair of Frogsmouth (Antirrhimum majus). It is a partitioned capitate hair.

several cellular projections, which in the lower figure, b, are represented spreading out in a star-like or stellate manner. A forked hair sometimes has the divisions hooked (uncinate), at other times barbed (glochidiate). In Figure 51 is seen a multicellular hair having a rounded top, and called capitate. Hairs are sometimes attached to seeds, as in the Cotton plant, for the purpose of scattering them. The cotton hairs consist. of elongated cells, the walls of which in drying collapse in the centre, so as to present a twisted appearance. Various parts of plants are transformed into hairs. Thus in Rhus Cotinus or the Wig-tree, the flower-stalks are changed into hairs, and in the common Dandelion and other composite plants,

the outer covering of the flower, called the calyx, assumes a hairy or pappose aspect. Hairs which have secreting cells at their apex, as in the Chinese Primrose, and in Sage (Fig. 52), are called glandular. The cells of the hairs occasionally secrete colouring matter, more especially when Glandular they arise from parts of the flower, as in the Iris and Virginian Spiderwort. When the cells of hairs are hardened by deposits, as in the Rose and Bramble, they are called Prickles (aculei). Bristles (setæ) are rigid hairs usually formed of a

Fig. 52. unicellular hair of Sal-via. The hair is called capi-tate, from

single cell; while stings (stimuli), as in the common Nettle (Fig. 48) and Chili Nettle, are stiff hairs arising from a series

of cells which secrete an irritating fluid. The scales produced Botany. on the leaves of Oleaster (Fig. 53), and of some Begonias, the

scurf on those of Bromelias, and the chaff (ramentum) covering the fronds of Ferns, are all modifications of epidermal cellular tissue.

Glands—are epidermal cells containing various fluid and solid secretions. They are either applied closely to the surface (sessile), as in the Ice-plant, where tney appear as elevations of the epidermis, containing a transparent fluid like ice, or in the Hop (Fig. 54), where they appear as resinous such saaly hairs or scale in Eleagnus, the Oleaster. Such soaly hairs of cont waxy and other rescretions. scales of different shapes; or they are raised on stalks (stipitate) of different lengths, and then may be called glandular hairs, as in the Sundew.

The bases of undeveloped hairs sometimes assume the

appearance of glands. The secretions of glands are of an oily, waxy, resinous, gummy, saccharine, saline, acid, or irritant nature. The honey-like matter of the flower is secreted by glands. In Figure 55 is represented one of the leaves of the flower of the Crown-imperial, showing the depression, g, at its base, in which the honey is se-

creted; a similar pit is seen in the common Buttercup. The cells at the base of the Nettle hair (Fig. 48) contain an irritant secretion, those at the apex of the Sundew hairs contain viscid matter. The glands on the flower-stalk of Dittany and Rose secrete oil, while those of the Chick-pea have an acid fluid in their interior. On the inner surface of the base of the stipules of Cinchona and allied genera, there are numerous small sessile glands which secrete a gummy matter.

CHAPTER II.

NUTRITIVE ORGANS OF PLANTS.

Having now considered the Elementary Tissues of plants, their composition, and contents, we proceed to view them in combination, as forming various compound organs. These are naturally divided into the organs destined for the nourishment or Nutrition of the plant, and those concerned in Reproduction, or in the formation of the new plant. as individual beings, plants present various aspects. Some,

like the Red-snow plant (Fig. 56), are composed of single isolated cells, which are capable of performing the functions both of nutrition and reproduction. Others, as Fungi and reproduction. Others, as rungi and sea-weeds, are composed of cells of the Red-snow plant numerous cells, united either in a linear series or as a flattened expansion, some of which are appropriated to the nutritive, and others to the reproductive functions.

The relaxation of the reproductive functions.

These plants are denominated Cellular. The higher classes of plants have cells and vessels Fig. 58.

trition and reproduction, and they are denominated Vascular.

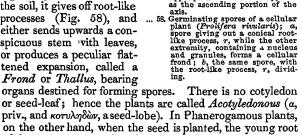

In the lower classes of plants there are no evident flowers -their organs of reproduction are obscure, and hence they are called Flowerless and Cryptogamic; while the higher classes have conspicuous flowers, and evident organs of reproduction, and hence are called Flowering and Phanerogamous or Phænogamous. In both classes the young plant, or embryo, in its earliest state, is cellular. This state

is retained by the embryo or spore (Fig. 8) of the former; while in the latter it assumes a high degree of development in the seed, and at maturity exhibits the parts which are to form the root, stem, and leaves, associated with certain temporary leafy

appendages or lobes, called cotyledons (Fig. 57).

When the spore of Cryptogamic plants is sown in the soil, it gives off root-like

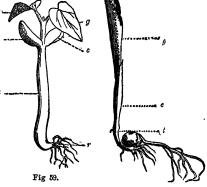

Fig. 57. Embryo contained in the seed of the Barberry. The lower portion of the axis gives origin to the radicle or young root which protrudes at the micropyle. The upper portion afterwards appears as the ascending portion of the axis. processes (Fig. 58), and ... 58. either sends upwards a conspicuous stem with leaves, or produces a peculiar flattened expansion, called a

of the embryo, proceeding from one end of the primary axis,

descends, while the stem ascends, bearing leaves and conspicuous flowers. This process is represented in Figure 59, where r is the young root coming off from the radicular end of the axis; and tis the stalk supporting the two cotyledons seed-leaves c c, t whence the plant is called Dicotyledonous (δis , twice); g g are the first leaves of

the plant. The same process is seen in Figure 60,

where the roots
are seen proceeding from the lower part of the axis t; the young stem is

seen in right out the radicular end of the axis; t, the stalk bearing the two cotyledons c c; the young stem is

marked g, and a single cotyledon or seed-leaf is seen at c; whence the plant is called Monocotyledonous (μόνος,

When we take a comprehensive view of the Vegetable Kingdom, we find that all the organs of plants are formed upon one harmonious plan. All are produced from cells, which are modified and aggregated in various ways, and are fitted for the special functions performed by the different parts of plants. The organs called Root, Stem, and Leaves, with their modifications, are those destined for nutrition or vegetation; while certain cellular bodies in Cryptogamic

Botany. combined, presenting more complicated organs of nu- plants, and the Flowers in Phanerogamous plants, are the Botany. organs of reproduction.

I.—ANATOMY OF THE NUTRITIVE ORGANS.

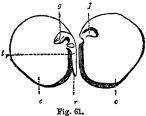

I.—THE ROOT OR THE DESCENDING PORTION OF THE AXIS.

The root (Fig. 59, r), generally speaking, is that part of the plant which descends into the soil, avoiding the light. It is the first organ developed from the axis of the embryo. The portion of the axis from which it arises is called radi-

cular. In Figure 61, the embryo of a Pea exhibits, at r, the portion of the axis from which the young root proceeds. This portion is called the Radicle; while the part t is connected with the ascending axis bearing the cotyledons (seed-lobes), c c, and the young stalk, g, which lies in a depression, f, of the cotyledons. The root consists at first entirely of cellular tissue; and, in cellular plants, this continues to be the cotyledons, f:

Fig. 61.

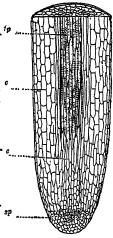

The Dicotyledonous embryo of the Pealaid open; c. the two fleshy cotyledons, or seed-lobes, which remain under ground when the plants whence the root arises; the axis bearing the young stalk and leaves, g, which lie in a depression of the cotyledons, f:

the case throughout life. In vascular plants it is strengthened by the addition of woody fibres and vessels, and presents the same internal structure as is seen in the stem. It may be considered a downward prolongation of the

The extremities of the roots are composed of loose cells, which appear to be the terminal tissue of the radicle, carried forward by the elongating root. These cells have been called Spongioles or Spongelets, but they ought not to be reckoned special organs. They do not consist of the newlyformed tissues, but they are in reality an annual mass of older cells, pushed forward by the root as it is developed. and when they decay, they are replaced by the layer be-

neath. Thus, according to Schleiden, the point of the root consists of older and denser tissue than that imme- 1p diately behind it. In the structure of the root we rarely meet with true spirals. The epidermal covering does not present stomata; but hairs, usually formed of a single elongated of cell, are produced, often in great abundance, which appear to serve the purpose of absorption. Figure 62 represents the magnified extremity of a young root of Orchis; o c c being the cellular tissue, passing into fusiform dotted cells and vessels, f p; the cellular extremity of the root, called the spongiole, being The extremities of sp marked s p. some roots, as those of Duckweed and Pistia, are covered by a nume cap-like process, or Pileorhiza, $(\pi i \lambda os, a cap, and pi (a, a root), which consists of a cellular layer, separating from the external parenchyma, but with <math>(\pi i \lambda os, a cap, and pi (a, a root), which consists of a cellular layer, separating from the external parenchyma, but <math>(\pi i \lambda os, a cap, and pi (a, a, a))$

arise from every part of the surface of the cellular axis or spore (Fig. 58), and hence the plants have been called by Richard Heterorhizal (ετερος, diverse, and ρίζα, root). In Monocotyledonous plants, the young roots arising from the raBotany. dicular portion of the axis separate into numerous fibres are sometimes covered, as in the Screw-pine, with a pe- Botany. \checkmark (Fig. 63, r), which, in piercing the axis, are covered with a

Fig. 63.

sheath (Fig. 63, co), called a Coleorhiza (κολεός, a sheath). These roots have been called Endorhizal, (evoor, within). Schleiden considers them as being adventitious. In Dicotyledonous plants the young root elongates directly from the extremity of the radicle (Fig. 64), and afterwards divides. It is called Exorhizal (ἔξω, outwards). These divisions of Richard are not adopted by Schleiden.

Roots have no proper leaf-buds; but in certain circumstances they are capable of producing them. Roots occasionally arise from different parts of the stem. Thus, when a cutting of willow is placed in moist earth, or branches are bent so as to be inserted into the ground, roots are given off, in the form of cellular prolongations, from the surface, or from small lenticular points to which the name of Lenticels has been given by some. Such roots are Adventitious, Secondary, or Abnormal. The term Aerial is given to roots which arise from the stem and branches of plants, and which, during the whole or part of their growth, are suspended in the air. Remarkable instances of these aerial roots are seen in the Banyan tree (Fig. 65), and in various other species of

Ficus (Urostigma) Indica, the Banyan tree, sending out numerous adventi-tious roots, which reach the soil, and support the branches.

Ficus; in the Screw-pine (Fig. 66), and in the Mangrove (Fig. 67), in Tree-ferns, and in some Palms, as Iriartea exorhiza. The extremities of these roots, when in the air, culiar cap-like covering. These abnormal roots ultimately reach the soil, and become subterranean, serving to support and prop up the trees to which they are attached.

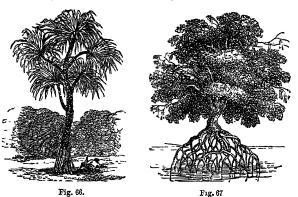

Fig. 66. Pandanus odoratissimus, the Screw-pine, giving off numerous aerial roots near the base of its stem.

... 67. Rhizophora Mangle, the Mangrove tree, supported, as it were, upon piles by its numerous roots, which raise up the stem.

The aerial roots of Iriartea are covered with numerous spines. In Epiphytes, or plants growing in the air, attached to the trunks of trees, such as Orchids, the aerial roots produced do not reach the soil. They continue always aerial and greenish, and they possess stomata. Delicate hairs are often seen on these Epiphytal roots, as well as a peculiar investment over their true epidermis. The aerial roots of the Ivy are not the proper roots of the plants, but simply processes intended for mechanical support.

Parasitic plants, as the Mistleto, Broom-rape and Rafflesia, send root-like processes into the substance of the plant whence they derive nourishment. In the Dodder,* the bark over the roots swells into a kind of sucker (haustorium), which is applied flat upon the other plant, and ultimately becomes concave, so as to attach the plant by a vacuum. From the bottom of the sucker the root protrudes which penetrates the supporting body. In the case of parasitic Fungi, such as mould, there are cellular filaments which spread among the tissues of plants, and which may be looked upon as equivalent to roots and stems united. They form the spawn or mycelium of these plants, and in some cases cause rapid destruction of the tissues of plants, as in the disease called Dry-rot.

Roots vary in their duration. In plants which grow up, flower, and die in one year, they are annual. In such cases they are usually composed of slender fibrils, which are deciduous, like leaves. These roots, consisting of numerous fibrils, springing from one point, are called Fibrous (Fig.

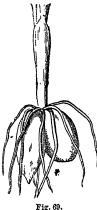

68). They are seen in many annual grasses. Plants which spring from seed one year, and flower the second season, and then die, have biennial roots; while those which continue to live and flower for many years, have perennial roots. In the last two cases the roots are often of a fleshy or woody consistence.

Perennial woody roots, when cut transversely, exhibit a structure similar to that seen in stems. Fleshy roots contain much starch, sugar, and gelatinous matter in their structure. They either descend singly, in an elongated tapering form, without branching, giving rise to various forms of branching, giving

Tap-root—conical in the carrot, fusionin of spindle-shaped in the radish, and napiform in spindle-shaped in the radish, and napiform in a fibrous—root of a grass. Numerous fibrils coming off *Pl. CXXI. roots, as in Ranunculus and Dahlia, and Tuberculate or Tu-

peculiar Annulated root, showing contractions at short intervals, while in Spiræa Filipendula the root becomes Nodose, presenting irregular swellings on its fibrils. Occasionally a Tap-root is suddenly arrested in its growth, and in place of tapering to a point, ends abruptly. This is seen in the Bittenrooted Scabious, the root of which is called Premorse. In some cultivated plants, as turnip, the central root is sometimes injured, so as to end abruptly, and it then divides into numerous branches, resembling a fasciculated root. This gives rise to the disease called Fingers and Toes, which is very injurious to the crop. The mode in which the fibres of roots are produced Orchis, and developed, thus gives origin to different forms of Rhizotaxis (bula, root, and rakes, order), or root-arrangement.

rchis, showing tuber-cules or tuberous roots, which contain a gummy matter called Bassorin.

II.—THE STEM OR THE ASCENDING PORTION OF THE AXIS.

1. Various Forms of Stems and Branches.

The stem is the ascending portion of the axis which is developed in an opposite direction from the root. It differs from the latter in usually seeking light and air, in bearing leaf-buds, which are produced at regular intervals, and in growing throughout its whole extent. In flowering plants conspicuous stems are met with, which differ in their texture, some being herbaceous, and dying down annually to the ground, others being woody and permanent, as in trees and shrubs. When stems are weak and trail on the ground, they are called prostrate or procumbent, when such stems rise towards their extremity they are decumbent, and when they rise obliquely from near the base they are ascending. Some stems are so slender that they require the aid of other plants for their support. They are either climbing and scandent plants, such as the Passion-flower, which clings to other plants by tendrils, or the Ivy, which adheres to rocks and walls by its root-like processes; or they are twining, when the whole stem coils round other plants in a spiral manner, the coils being either from right to left, i.e., to a person supposed to be in the centre of the coil, and the stem twining across his chest from his right to his left, as in Convolvulus, Phaseolus vulgaris, and Dodder; or from left to right, as in the Hop and Tamus.

Names are given to plants according to the nature and duration of their stems. Herbs, or herbaceous plants, have stems which die down annually. In some of them the whole plant perishes after flowering; in others, the lower part of the stem forming the crown of the root remains, bearing buds, from which the stem arises next season. In what are called biennial herbs, the whole plant perishes after two years, while in perennial herbs the crown is capable of producing stems for many years, or new annual products are repeatedly added many times, if not indefinitely, to the old stems. The short permanent stem of herbaceous plants is covered partially or completely by the soil, so as to protect the buds.

Plants producing permanent woody stems are called Trees and Shrubs. The latter are less than five times the height of a man, and produce branches from or near the ground; while the former have conspicuous trunks, which attain at least five times the height of a man. Shrubby plants of small stature are called *Under-shrubs* or *Bushes*. The limits between these different kinds of stem are not always well defined; and there are some plants occupying

Botany. berous roots, as in Orchis (Fig. 69). In Ipecacuan there is a an intermediate position between shrubs and trees, to which Botany. the name of arborescent shrubs is occasionally given. The usual name given to the herbaceous stem is Caulis; in grasses the stalk is called a *Culm*; while in Palms and Tree-Ferns the stem is denominated *Caudex* and *Stipe*.

Stems sometimes assume anomalous forms. In the Tortoise-plant, or Elephant's-foot-plant, the stem forms a large irregular thick mass, with a rough and tuberculated exterior. In the Melon-Cactus it is globular, in other species of

Cactus, it is jointed, columnar, or angular; while in many Orchids (Fig. 70) it assumes an oval or rounded form, and is called a Pseudo-bulb. The stem is so short in some plants, as the Primrose, Cowslip, Gentian, and Dandelion, that they are called Stemless or Acaulescent. A similar term is given in ordinary language to plants whose stems are buried in the soil, such as Cyclamen or Sow-

The stem, although it has a tendency to rise upwards when first developed, in many instances becomes prostrate, and either lies along the ground, partially covered by the soil, or runs completely An underneath its surface, giving off roots from one side, and buds from the other. Some stems are therefore subterranean,

and are distinguished from roots by the provision made for regular leaf-buds.

The points where leaves or leaf-buds are produced are called Nodes. In certain jointed stems or branches, as the Bamboo, these are well marked; but in stems which are not articulated, the nodes are often distinguished chiefly by the leaves which they bear, or by the scars left after their fall. The intervals between the nodes are denominated Internodes, and they are of different lengths, according to the distance at which the leaves are placed from each

The stem may be considered as formed of a series of leaves, at first closely aggregated on a shortened axis, and afterwards separated by more or less evident intervals. As the leaves decay and fall off, the stem becomes more conspicuous and uninterrupted. Buds may be regarded as shortened leaf-bearing axes, capable of elongation, so as to form stems and branches, with nodes and internodes. Some buds are terminal, or are produced at the extremity of the primary axis, just as the first bud in the Embryo-plant. These buds in their after-growth continue to add to the length of the stem. Other buds are lateral, or are produced on the sides of the axis. These are concerned in the production of branches.

In trees which do not ramify, as most palms, there are no lateral buds. In plants which have permanent stems, and in which the leaves are deciduous, provision is made for subsequent growth, by the production of buds which lie dormant during the winter, or the season of repose, and are ready to burst forth when the spring or the rainy season returns. The buds are situated at the angles where the leaves join the stem, or in what is called the Axils of the leaves. In cold and temperate climates these buds are protected by a coarse external scaly covering, and sometimes also by a waxy, glutinous, or resinous matter, as is well seen in the Horse-chestnut.

Buds, in place of producing branches, are in some instances abortive, or remain latent, ready to be developed when any injury has been inflicted on the terminal buds or branches. Occasionally, after a partial development as branches, buds are arrested and form knots or nodules. The embryo-buds or nodules of the Beech, Cedar, and Olive, are apparently of this nature. Sometimes several

Botany. buds unite together in the axil of a leaf, and form a peculiar flattened branch.

Branches are sometimes long and slender, and run along the ground, producing roots and leaves at their extremity or apex. This is seen in the Runner (flagellum) of the Strawberry. In the Houseleek (Sempervivum) there is a similar prostrate branch of a shorter and thicker nature, producing a bud at its extremity capable of independent existence. It receives the name of Offset (propagulum). A Stolon differs from these in being a branch which curves towards the ground, and, when reaching a moist spot, takes root and forms an upright stem, and ultimately a separate plant. It is a sort of natural layering, and the plant producing such branches is called Stoloniferous.

Spines or Thorns are usually abortive branches ending in sharp points. This is shown by their producing leaves occasionally (Fig. 71), and by their being frequently changed into ordinary branches during cultivation. Plants bearing thorns (modifications of branches or leaves) are denominated spiny, spinose, or spinescent. Tendrils (cirrhi) are frequently an altered state of leaf-buds or branches, as in the Passion-flower and the Vine, enabling the plants to climb. In the Vine, as represented in (Fig. 72), the ten-

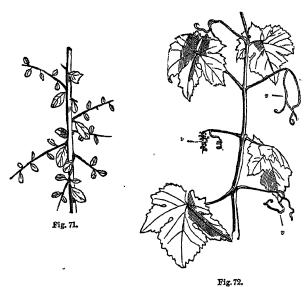

Fig. 71. Branch of the Sloe (*Frunus spinosa*), producing spines or thorns, which are abortive branches, as shown by their bearing leaves.

... 72. Part of the stem of the Vine, showing the formation of tendrils, each of which are considered as terminating axes. Between each leaf and tendril a bud is given off which forms an axis ending in a tendril, v.

drils, v v v, are considered by some as the terminations of separate axes. The lowest leaf in the figure is connected with the first axis, which ends in a spiral tendril, v; and between this tendril and the leaf a bud is given off, forming a second axis, which ends in the second tendril, v_i between which and this second axis another bud is given off, forming a third axis, ending in a third tendril, v, and so on. The different axes are in this case called cirrhose.

Subterranean Stems and Branches are sometimes short and thick, at other times they are elongated. Some are completely under ground, while others are only partially so; some increase by lateral, others by terminal buds. Many of them are in the ordinary language called roots, from which, however, they are distinguished by the power of forming regular buds, or by having rudimentary leaves or scales on their surface. Many of them contain much nourishing matter, which is stored up for the future growth of the plant.

Rhizome, or root-stock, is the name given to certain root-like forms of creeping stems, which are more or less

completely subterranean. They are seen in Iris, in Ginger, Botany. and Convallaria (Fig. 73). Such stems exhibit on their upper surface the marks or scars of leaves, and it is to the scale-like appearance of these markings that the plant called Solomon's seal (Fig. 73) owes its name. Of a similar nature is the Soboles, or creeping stem of Carices, Papyrus, and other grass-like plants, which spread through the sand and loose mud in such a way as to bind the particles together.

In the Banana (Fig. 86), there is an underground stem which sends Rhizome, root-stock, or par-up shoots of a herbaceous na-ture to bear the flowers and the stem of Solomon's send (Poly-gonatum multipliorum).

fruit. In Asparagus the shoot developed from the subterranean stem is called a Turio; it is the part used as an article of diet; at first it is covered with scales, but it afterwards gives off branches, which bear leaves, flowers, and fruit. In the Rose and Mint a subterranean branch arises from the stem, which runs horizontally to a certain extent, and ultimately sends up an aerial stem, which becomes an independent plant. Such branches are denominated Suckers, and the plants are called Surculose. The gardener divides the connection between the sucker and the parent stem, in order to propagate these plants.

The Tuber is a subterranean branch, which is arrested in its growth, and becomes remarkably thickened, in place of being elongated. It is seen in the Potato and Jerusalem Artichoke; and the eyes produced in these instances are true leaf buds. When the older parts die away, these tubers are found to belong to one axis with the new structures, which are subsequently formed. In the Arum,* Col- * Plate

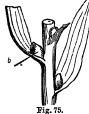

chicum, and Crocus, the tubers are perfected after the other CXXXV. parts, which belong to the same axis with themselves, so that they and the new structures belong to two axes, or at least to two different processes or shoots of the same axis. Such tubers are called Corms. They have a central axis, which is sometimes covered by thin scales; and they may be looked upon as shortened axes with scaly leaves, or as subterranean buds. Corms may be regarded as dilated stems intervening between the first buds and the roots. They give off buds in the form of young corms, and occur in monocotyledonous plants. In Gladiolus, the new corms are so superimposed upon each other, that they gradually rise above ground. In Colchicum (Fig. 74) the new corm, b, is produced alternately at either side of the old one, a, which shrivels. Sometimes three generations may be seen at the same time-the old corm, the new corm, and the bud of next year.

The Bulb is also a short subterranean axis, which is covered with fleshy scales containing succulent cells. It is a bud produced under ground, the centre corresponding to the axis, which is clothed with scales, and which sends flowering stems upwards, and roots downwards. In the Lily the thick and narrow scales are arranged separately in rows, and the bulb is called scaly; while in the Leek the scales are broad, and inclose each

other in a concentric manner, the outer ones being thin and membranous, and the bulb is said to be tunicated. The scales are equivalent to leaves, and they produce buds in the form of cloves or young bulbs at the part where they join the axis. At the base of the bulbs there is a flattened rounded por-

tion, which produces roots from one side, and scales and leaves from the other. The central bud produces the flowering stem. The lateral buds or cloves sometimes remain attached to the axis, and produce flowering stems, so that the same bulb continues to flower for many years, as in the Hyacinth and Tulip; at other times the young bulbs are detached, and form separate plants. In the case of some form separate plants. In the case of some plants, as Lilium bulbiferum (Fig. 75); bulbs are also produced on the stem, in the form of bulbels or bulblets, b, which are scaly buds, capable of being detached, and of forming independent plants.

2. Internal Structure of the Stem.

The forms of the stem having been considered, we now proceed to examine its anatomical structure. This structure consists of the elementary tissues combined and arranged in various ways. In some plants the part which serves the purpose of a stem is composed entirely of cells arranged in the form of very narrow filaments, which are simple or branched, as in some Fungi* and Confervæ, or which form an CXXXVI. expanded surface, called a Thallus or frond. Such cellular plants have received the name of Thallogens or Thallophytes (θαλλος, a frond); while those producing stems composed both of vessels and cells are sometimes called Cormogens or Cormophytes (κορμος, a stem or stipe). In ordinary conspicuous stems, both cellular and vascular tissue are present.

> The arrangement and development of the cellular and vascular systems give rise to three marked forms of stems: -1. Acrogenous, in which the bundles of vessels are simultaneously developed, and the additions to the stem take place at the summit, by the union of the bases of the leaves. Plants having this kind of stem are called Acrogens (akpos, summit, and yevvaew, to produce), or Summit-growers. Tree-ferns furnish an example. 2. Endogenous (ἐνδον, inwards), in which the bundles of vessels are definite, and are deposited towards the centre, which becomes filled up with them in the progress of growth, so that the diameter of the stem increases in a great measure by the new matter pushing out that previously formed. Such plants are called Endogens, or Inside-growers. Palms and Screw-pines supply examples. 3. Exogenous (ἔξω, outwards), in which the bundles of vessels are produced indefinitely in an outward direction, and the stem increases in diameter by the annual formation of a new layer of woody matter formed on the outside of the preceding layers. Such plants are called Exogens, or Outside-growers. Ordinary trees, such as the Oak and Ash, furnish instances.

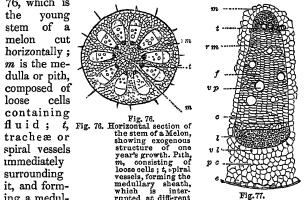

While the structure of the stem supplies obvious characters, it will be found that other distinguishing marks separate these three great classes of plants even in their earliest state. Thus, Acrogens are Acotyledonous (Fig. 58); Endogens are Monocotyledonous (Fig. 60); and Exogens are Dicotyledonous (Fig. 59).

a. Exogenous Stem or the Stem of Dicotyledonous Plants.

Exogens are the largest class of plants in all parts of the globe, and the structure of their stems is familiar to us in the trees of cold and temperate climates. In Britain the trees of our forests are all exogenous in their formation. Such trees, however, occur also in warm regions, associated with others exhibiting endogenous and acrogenous structures.

An exogenous stem, in its earliest condition, is entirely Botany. cellular. When the plant begins to grow and send up its first leaves, the cellular tissue of the axis is seen to be traversed by bundles of vessels (vascular bundles), which soon divide the stem into two marked portions; an internal, forming the central pith or medulla, and an external, forming the cortical pith or bark, covered by epidermis. The connection between the central pith and cellular bark is kept up by means of lines of cellular tissue, called medullary rays, which are interposed between the vascular bundles. At the end of a year's growth, we observe, in the exogenous stem, a central cellular pith, a circle of vascular bundles in the form of wedge-shaped masses, an external bark and integument, and rays passing from the pith to the bark. This is the complete structure of exogenous herbaceous stems, which die down annually. The appearance is exhibited in Figure

76, which is young the stem of a melon cut horizontally; m is the medulla or pith, composed of loose cells containing ing a medullary sheath; r m, medullary rays, composed of more or less flattened cells, which extend from the pith to the external cellular bark or

which is interrupted at different points to allow medullary rays, rm, to pass from the pith to the bark. The medullary rays divide the stem into ten wedge-shaped vascular bundles, the outer part of the bundles forming the fibrous layer of bark, and the inner constituting the wood; the pitted vessels are represented by large round openings. The circumference is the outer portion of the bark, consisting of cells which are covered by the general integument bearing hairs.

hairs.
77. One of the vascular wedges of the Melon separated to show its composition; m, medulla or pith; t, spiral vessels of medullary sheath; r m, medullary ray; f, woody fibres; v p, pitted vessels; c, cambium cells between wood and bark; l, inner bark, consisting of woody fibres, and called endophiœum; v l, latioferous vessels; p, c, cellular envelope of the bark; c, general integument.

cortical layers; on the outside of the bark is the integument with projecting hairs, and between the medullary rays are ten wedges of fibro-vascular bundles, consisting of woody, porous, annular, reticulated, and spiral vessels; in these wedges the porous vessels are represented by large rounded openings. In Figure 77 is given a horizontal section of one of the fibro-vascular bundles, in order to show its composition. The section extends from the pith to the outer integument; m, medulla or pith; t, tracheæ or spiral vessels, forming the sheath round the pith, the fibres being unrollable; r m, cellular medullary ray at the side of the vascular wedge; f, woody, annular, and reticulated vessels; v p, porous or pitted vessels of large calibre; c, a layer of green and active cells, forming what is called the cambium layer; I, woody fibres, constituting a layer called the inner bark; v l, ramifying laticiferous vessels; pc, cortical cells, constituting the cellular bark, which is covered by the common integument, e.

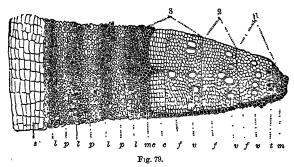

In stems which are not annual, the growth of the second year consists of a new formation of vascular bundles outside the previously formed layer, between it and the barkthe connection between the pith and the bark being still kept up by cellular rays. Between the pith and the bark there are annually formed a layer of active formative cells, called cambium cells, which are concerned in the development of new woody fibres. In Figure 78 is shown a transverse section, A, and a vertical section, B, of one of the

of the second year of growth —the letters referring to both sections; t, tracheæ, or spiral vessels, forming the medullary sheath, which allows the medullary rays to pass through at different points; v p, porous or pitted vessels, constituting bothrenchyma or taphrenchyma, and presenting large rounded openings; f, f, fibres formed of fusiform tubes, the inner, f, marking the fibres forming the wood of the stem, and the outer, f, those which form the cortical fibres of the inner bark; c, cambium cells between the wood and bark; p c, p c, cortical polyhedral cells, often of a greenish colour, forming a cellular layer of bark; s, outer cellular layer of bark, composed of cubical or tabucomposed of cubical or tabular colourless cells, often of a Corky nature, and hence called suberous; this cortical layer is covered by the general integument. Thus, at the commencement of the second year's growth. Thus, at the commencement of the second year's growth there is a distinct formation of cambium cells, by the action of which a new layer of fibrous bark is formed: and these cambium cells height growth as distinct from the cellular layer below; on the cut-side of the suberous layer is the second year's growth as distinct from the cellular layer below; on the cut-side of the suberous layer is the second year's growth; p.o. p.e., constituting the inner bark (liber or bark (Epiphlœun); s. suberous layer of bark may be action of the stem of a Maple at the commencement of its second year's growth. A, Horizontal section; B, Vertical section, Spiral vessel vertical section, Spir

formed; and these cambium cells, being in connection with the medullary rays, keep up the connection between the medullary and cortical cells.

Fig. 78.

Let us now trace the changes which take place in the permanent woody stem of the Maple, after three years' growth, as represented in Figure 79. The yearly growth

Horizontal section of one of the vascular wedges of the Maple, taken from a stem three years old.

of the woody bundles is marked by the Figures 1, 2, 3:-1. The Pith, m, is surrounded by tracheæ, t, which are not repeated in the growth of subsequent years; outside these are the pitted vessels, v, and fibrous tissue, f, of the first year's growth. 2. Pitted vessels, v, and fibres, f, or woody and other vessels of the second year's growth. 3. Pitted vessels, v, along with fibres, f, of third year; c, layer of cambium cells outside the wood of third year. The outer part of the section consists of the layers of bark; s, the suberous, or outer layer of bark cells; immediately within, is p, the cellular layer, and l l, the fibrous layer of the bark of the first year; then follows the bark of the second year, p l; and, finally, the cortical layers of the third year, p l, which VOL. V.

Botany. fibro-vascular bundles of the maple at the commencement are separated from the wood by a cortical layer of new cells, Botany. me, and the cambium layer, c.

> In examining, therefore, the growth of an Exogenous stem, it will be seen, that while additions are yearly made to the layers of wood in an outward direction, so as to give rise to the term Exogen, or outside-grower, the bark, on the contrary, increases by annual additions on the inside. The increase of the diameter of such stems takes place by successive deposits of vascular wedges in concentric circles, year after year, and during this growth the bark becomes gradually distended. On examining old stems the different annual layers can be counted, especially in trees of cold and temperate climates, where there is a marked cessation of growth during winter.

> Let us now proceed to examine the different parts of an Exogenous stem proceeding from the centre to the circumference.

The Pith (Fig. 76, m)—consists of cellular tissue (parenchyma), at first succulent, but afterwards becoming dry, as its juices are absorbed for the use of the young plant. The dry pith of the stem is sometimes used for paper, as in the case of Rice paper or Schola, which is produced in India from the stem of Æschynomene paludosa, in the Malay Archipelago from that of Scævola Taccada, and in China from that of Aralia papyrifera (Tung-tsaou). the progress of growth its cells are sometimes broken up, so as to form large empty cavities, as in the Walnut, Poke, Jessamine, Horse-chestnut and Hickory; at other times the whole pith gives way, owing to the rapid distension of the outer part of the axis in its early state, and then the stem becomes hollow, with shreds of pith attached to its interior, as in Umbelliferæ* and Grasses. The cells of pith *Pl. CXX are well seen under the microscope in the Elder.

The Medullary Sheath—is the first formed vascular layer (Fig. 77, t). It consists principally of spiral vessels (Fig. 30), the fibres of which can be uncoiled. This is the only part of an exogenous stem in which these vessels ordinarily occur. This medullary circle is not always complete, spaces being left between the vessels where the medullary rays and the pith communicate. The tracheæ traverse the cellular tissue so as to reach the leaves.

The Wood.—The layers of wood (Fig. 77, f) are formed outside the medullary sheath. They consist of woody fibres (prosenchymatous tubes) such as those represented in Figure 24, mixed with dotted ducts (Fig. 3), and occasionally with a few annular (Fig. 32) and reticulated (Fig. 33) vessels belonging to the spiral type. On making a transverse section of the stem of the Chestnut, Ash, or Oak, the extremities of the dotted ducts (pitted vessels) will be seen in the form of large rounded openings on the inner side of the woody circle or zone. In the Maple (Fig. 79), Plane, Lime, and Hornbeam, the openings are large, and are diffused throughout the annual zones, mixed with pleurenchyma. In coniferous (cone-bearing) plants, as the Fir and Pine, the woody layers are composed of disc-bearing pleurenchyma (Fig. 25), without any dotted ducts, and hence under the microscope no large rounded openings are seen in the woody lavers.

In the young state the pleurenchymatous tubes of the woody zones are pervious, but by degrees they are obliterated by the deposits of ligneous matter (lignin). In old exogenous trees the central wood is hard and durable, constituting the Heart-wood or Duramen, while the exterior wood is soft, forming the Sap-wood or Alburnum. The lignin deposited in the heart-wood frequently acquires a marked colour, as in the Ebony tree, where it is black; in the Black Walnut, where it is dark-brown; in the Barberry and Judas-tree, where it is yellow; in the Red Cedar,where it is purplish-red; and in the Guaiac tree, where it is greenish. The relative proportion between alburnum and duramen varies in different trees. Those in which the hard

Botany. wood predominates are best fitted for building, and for withstanding the effects of moisture, dry rot, and the attacks of insects and other animals. The durability of woods depends on the nature of the ligneous matter deposited in their pleurenchyma, and this varies much.

The woody zones annually formed are not always of the same size. Much depends on the state of the climate and season, the exposure of the plant to air and light, and the nourishment which it receives. A narrow ring of wood may be considered as recording a cold season, while a wide one indicates a warm season. The same zone also varies in size at different parts, so that, in many cases, the pith is excentric-that is, not exactly in the centre of the stem, owing to the circles being thicker on one side than on the other. Bravais and Martins noticed a Scotch Fir in which the two semi-diameters of the stem were to each other as nine to nineteen, or the one more than double the other. In such cases, it usually happens, that the side of the tree having the greatest thickness is that which has been best exposed to

From the mode in which layer after layer of wood is formed, it follows that the age of an exogenous tree may be estimated by counting the number of woody circles (Fig. 80.) In trees of cool climates, where there is a marked

cessation of growth, this may be done with tolerable accuracy up to a certain age at least; but in trees of warm climates, where there is a less marked period of repose, this cannot always be done accurately. It is said that in some of the trees of tropical America monthly circles are formed; while in species of Cactus and Cycas more than one year is required to form a single year is required to form a single

zone. In estimating the age of trees in temperate climates, the rings or zones of woody matter must be counted from the pith to the bark. Mistakes have been committed, in many instances, by merely making a section of the stem of an Oak, showing the pith in the current the woody layers formed in concentric circles around it, and the layers of bark on the outside. There are six woody circles, indicating that the stem of the same age is indicated by that the stem of the distribution of the distribution of the distribution. and then estimating from their size for the whole diameter of the tree.

Fig. 80.

The Medullary Rays.—These connect the pith and the bark (Fig. 76, r, m). They consist of flattened quadrangular cellular tissue, having an appearance like bricks in a wall, and hence called muriform. In the young stem these rays are large, while in the more advanced woody stem they are seen as lines only. They constitute the silver-grain so conspicuous in the Maple, and they give the peculiar silvery lustre to many woods when cut in the direction from the pith to the bark. These rays do not proceed in a continuous plane from the top to the bottom of the tree. They pass through the woody layers in such a way as to be interrupted in their course, and when a section is made perpendicularly to the rays, or, in other words, as a tangent to the circumference of the stem, their ends are seen projecting irregularly through the woody fibres. They are said by some authors to represent the horizontal system of the stem, or, as it were, the woof, which is traversed by the vertical woody bundles, like the warp. The medullary rays are in some cases, as in Clematis and Aristolochia, large and broad, while the woody wedges are comparatively small. Besides complete medullary rays, there exist others which only extend partially through the stem.

The Cambium Layer.—This is a layer of nucleated cells, lying between the wood and the bark, and originally connected with both. They are formed in a mucilagmous fluid

called Cambium, and they are concerned in the formation Botany. of the woody tubes of the inner bark, and of the pleurenchyma, as well as in the additions made to the cells of the medullary rays. When these cells are carrying on the process of growth with activity, during the flow of the sap in spring, the bark can be easily separated from the

The Bark—is at first composed of uniform cellular tissue, resembling that of the central part of the stem (Fig. 77). In the progress of growth transformations of the tissue take place, by which fusiform prosenchymatous tubes are formed in the inner portion of the bark next to the woody circle. This portion is called the Inner Bark or Liber (Endophlæum -ἐνδον, within, and φλοιὸς, bark). It consists of thickened pleurenchyma with some laticiferous vessels. It is the fibrous part of the bark, and is often called Bast tissue. The fibres of the liber are long and tenacious, and are employed for various useful purposes. Those of the Lime-tree, Hemp, Mallow, Hibiscus, Boehmeria, Nettle, and Daphne cannabina, are employed for different articles of manufacture. The fibres sometimes separate, so as to form meshes, as in the Lace-bark tree. The inner bark of Antiaris saccidora has tenacious fibres, which are used in India for cordage and matting. The tree is common in the jungles near Coorg, according to Dalzell, and the people manufacture curious sacks from it. A branch is cut corresponding to the length and breadth of the sack wanted. It is soaked a little, and then beaten with clubs until the liber separates from the wood. The liber, in the form of a sack, is then turned inside out until the wood is sawed off, with the exception of a small piece left to form the bottom of the sack. These sacks are in general use among the villagers for carrying rice. The inner bark of various trees has been used for writing upon, and hence the name liber.

On the outside of the liber lies the cellular portion of the bark, consisting of two layers, the Cellular Envelope, called also Mesophlœum (μέσος, middle), and the Corky or Suberous Envelope, called also Epiphlœum (ἐπὶ, upon, on the outside). The former is composed of loose thin-walled polyhedral cells, containing chlorophyll, and hence often denominated the green layer; the latter consists of flattened tabular parenchyma, giving the peculiar colour to the branches and young stems of trees and shrubs. The epiphlœum is rarely green; it is generally some shade of ash-colour or brown. It is sometimes developed to a great extent, constituting the cellular substance called cork, procured from the Cork-oak, and produced also by various species of Elm. In some trees the epiphlœum falls off at certain intervals. In the Cork-oak it does so in eight or nine years, leaving a tabular layer of cells below. In the Birch the outer bark is the part which separates in layers, owing to the formation of a stratum of thin-sided cells below the lamellæ, which easily separate into fine powder when disturbed. On the outer surface of the epiphlœum is the Epidermis, or general integument, which in old trunks is thrown off.

The different layers of bark increase by additions of new cells to their inner surface. The cellular layers, however, soon cease to grow, while the liber continues to increase by additions from the cambium layer. The thickening of the pleurenchyma of the liber takes place by concentric deposits of lignin, in the same way as in the case of woody tubes. Sometimes the different annual circles of bark may be traced, but in general, after a certain length of time, all the layers are more or less amalgamated by the growth and pressure of the parts below, so that it is impossible to ascertain the age of the tree by the cortical layers. It is obvious that, by the constant additions to the wood on its outside, and the bark on its inside, the latter is distended, and when the cellular portion has ceased to grow, it cracks and splits in various ways, and ultimately falls off. The distension and

Botany.

Botany. increase in diameter of an Exogenous stem is such, that a woody climbing plant, for example Bauhinia or Honeysuckle, when surrounding it, gives rise to marked grooves on the surface, and often arrests its growth entirely by pressure on the sap wood.

Although all these parts are generally observed in Exogenous stems, and present the order now mentioned, still, various peculiarities occur, especially among exogenous trees

of warm climates, which often obscure the arrangement. Thus, in some trees of great age only one marked zone or circle of woody matter is seen, consisting of a series of separate wedges; in other trees there are several such zones, each of which is the produce of more than one year's growth. In such cases the stem increases in diameter by the formation of new wedges, or by additions to the old ones. Occasionally the woody matter is so formed as to be in separate masses, surrounded by cellular tissue, which pre-

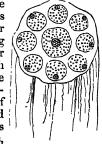

Fig. 81.

sents the same appearance as the outer bark (Fig. 81). Such a stem looks as if it was formed by several united together.

Some Exogenous plants with twining stems become much altered by compression; other exogens exhibit fluted stems. In the Yarroura wood, or Paddle-wood (Aspidosperma excelsum), the stem is singularly fluted, and presents a waved or sinuous aspect. The same kind of appearance is seen in some woods which are imported for the purpose of furnishing dyes, such as Logwood, Nicaragua wood, and Rio de la Hache wood (Cæsalpinia echinata), &c.

The Branches of Exogens.—In Exogenous stems a provision is usually made for the formation of branches, or, in other words, the stems grow, not merely by producing buds at the apex, which cause an increase in height, but also by lateral buds which give origin to branches. These are connected with the centre of the stem, and their tissues can be traced to the pith and its sheath. From this mode of growth Exogenous trees have a form more or less tapering as regards their stem and branches. In the arrangement of their parts, branches resemble the stems from which they proceed. When regularly developed they taper to a point, and continue to produce buds, which again form smaller branches and twigs by constant subdivision.

The mode in which branches grow and subdivide gives rise to different aspects in forest trees. In the Cedar, the branches spread nearly at right angles; in the Italian Poplar they come off at an acute angle with the upper part of the stem; in some plants, as the Weeping Elm, they come off at an obtuse angle. In the Birch and Willow the branches become so slender at their extremities that they bend by their own weight. When the terminal bud of a stem or branch of an Exogen is cut off or arrested in its growth, the lateral buds are produced abundantly, and thus give rise to the appearance seen in pollard trees, and in the clustering of the twigs of the Birch and other trees. The comparative length of the branches in the upper and lower parts of trees tends also to give them a peculiar physiognomy. When the lowermost are longest, and the others are gradually shorter as we proceed upwards, the conical form is produced, as seen in the Douglas Pine (Abies Douglasii). When the uppermost are longest, as in Pinus pinea, the form is somewhat like that of an inverted cone. When branches are produced under ground, and in darkness, they frequently become thickened and contorted in various ways, as seen in the potato, the tuber of which is a branch of this kind. When the potato is allowed to grow above ground, but in darkness, the ordinary branches sometimes assume the form of tubers.

b. Endogenous Stem, or the Stem of Monocotyledonous Plants.

This kind of stem is not seen in its fullest development in northern climates. We must look to the Palms and Screw-Pines of warm regions, in order to see the striking effect produced by its mode of growth. The trunks of palms differ much in their aspect from the trees of this country, They have usually simple unbranched, cylindrical stems, towering to a great height, and covered by a large mass of remarkable foliage (Fig. 82).

In the structure of the woody endogenous stem there is no marked distinction between pith, wood, and bark; there are no medullary rays, nor concentric circles. Definite vascular bundles are diffused through the cellular tissue without apparent regularity, and the whole is enclosed by an external covering which differs from the bark of Exogens, in not having annual layers, and in not being separable from the wood. In Figure 83, which exhibits a transverse section of a Palm-stem, this arrangement of tissues is seen. On the outside is the cortical portion not separable from the rest; the vascular bundles are marked f, and the cellular portion, which is looser towards the centre, m. In the early state the stem is entirely cellular, but in the progress of growth vascular bundles are produced, consisting of woody, spiral, dotted, and laticiferous vessels. In Figure 84, there

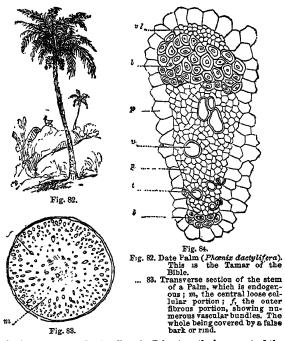

Fig. 84. One of the vascular bundles of a Palm-stem, the lower part of the figure being that next the centre. Upper p, the general cellular parenchyma surrounding the bundle; lower p, woody fibres; ll, ilbrous thickened woody vessels, resembling those of the liber of exogens; t, trachem (spiral vessels); v, large dotted wessels; v l, lationferous vessels.

is represented a transverse section of one of the fibro-vas cular bundles of an Endogenous stem; upper p marking the general cellular parenchyma surrounding the bundle; lower p, woody fibres; l, woody vessels analogous to those of the liber; t, tracheæ (spiral vessels); v, dotted vessels of large calibre; v l, laticiferous vessels. The vascular bundles are most abundant near the circumference, while the cellular tissue is in larger quantity in the centre. In the bundles the woody vessels (Fig. 84, 11), generally surround the other vessels.

The vascular bundles may be traced from the leaves downwards, some proceeding more or less directly towards

Botany. the root, others curving outwards towards the cortical integument or rind (Fig. 85, fv). The mode in which these bundles proceed from the leaves towards the centre, in the first

instance, has given rise to the term Endogenous, or inside-growers; the idea originally entertained by physiologists being, that the vascular bundles were always produced on the inside of those which preceded them. The bundles, however, although they have a tendency towards the centre at first, do not always remain there, but follow a curved course towards the periphery, and in this way the outer rind becomes completely incorporated with them, so as not to be separable. The structure of the bundles varies in different parts of their course. Near

Tig. 85.

Vertical section of a Palm-stem, so their course. Near

Tig. 85.

Vertical section of a Palm-stem, so their course. Near

Tig. 85.

the base of the leaves they contain all the vessels already mentioned, but as we trace them downwards, the spiral, dotted, and laticiferous vessels disappear, and the woody fibres alone remain when they reach the rind, or, as it is often termed, the false bark.

From the mode in which the vascular bundles are added, it will be seen, that the tendency is to push the older vessels outwards, and to render the periphery hard. In Palms, therefore, the hardest part of the stem is external, which is the reverse of what takes place in Exogens. By the internal addition of vascular bundles from terminal buds only, and by the interstitial growth of cells, the stem of a Palm increases in diameter until it acquires the full limit to which the outer rind can be distended, and attains ultimately a uniform diameter throughout. Thus, there appears to be a definite limit to the lateral growth of a Palm, while no such limit can be seen in the case of Exogens, in which vascular bundles go on increasing indefinitely, and the bark is se-Palms consequently do not exhibit trunks of a diameter equal to that of Exogenous trees, nor does their bole present a tapering form. The first part of the stem of a Palm is formed by vessels which are connected with the first crown of leaves; the next crown, or terminal bud, produces more woody bundles internal to the first, and thus the stem is thickened during successive seasons, until at length the lower part is fully formed. The same process goes on throughout the whole stem, until it acquires a continuous cylindrical form. From the structure and mode of growth of a Palm-stem, it follows, that a woody twining plant does not produce the same injury as in the case of an Exogen.

Palms grow in a uniform manner as regards height in their native countries, and their age may in general be de-termined by the length of their stem. The destruction of the terminal bud of the Palm stops its growth, in consequence of the want of provision for lateral buds. In some instances, however, as is particularly seen in the Doum Palm of Egypt (Hyphæne thebaica), branches are given off in a forked, or what is called a dichotomous manner. There are also many endogenous stems which produce lateral buds. The Screw-Pine (Pandanus), for instance, and species of Dracæna, have branching stems. In the Dragon trees (Dracæna), a remarkable increase of stem takes place in consequence of the cortical integument remaining soft, and capable of unlimited distension. The vascular bundles, after reaching the circumference in these plants, descend towards the root, and being produced both by terminal and lateral buds, they are developed in large quantity, and thus give rise to enormous stems. Such a stem is seen in the famous Dragon tree of the Canaries, which near the ground is 70 feet in circumference. When numerous buds are produced laterally, the lower part of the stem receives more bundles than the upper,

and thus the stem tapers. This is seen in the Asparagus Botany. and Bamboo, which in this respect resemble Exogens.

In some Endogenous stems the rapid growth of the outer part gives rise to a rupture of the central cells, and thus the hollow stems of many grasses are produced. In the Bamboo the hollow cavities in the stem are separated by partitions formed by the crossing of the vascular bundles. In Xanthorrhœa Hastile, the grass-tree of New Holland, a liliaceous plant, the structure of the stem and branches is peculiar. On making a vertical section the structure appears to be that of an Exogen. The woody part is formed of vertical loose fibres like Palms, and there are other fibres, radiat-

ing from the centre, and cutting the preceding at right angles. These horizontal fibres resemble the medullary rays, but differ in their structure. They probably serve for the origin of leaves, which are numerous, and are disposed throughout the whole length of the stem.

Endogenous stems sometimes remain under ground. The corm is in fact a shortened endogenous subterranean stem. Bulbs, are under-ground endogenous stems, covered with scales. In the Banana (Fig. 86), as well as in the Asparagus, the true stem is subterranean, Banana (Musa septentum), having an unand sends up shoots bearing leaves. flowers, and send-ing up a herbaceous shoot, which bears leaves, flowers, and fruit.

Fig. 86.

fruit, which, after dying down, are succeeded by other shoots. The peripherical portion of some subterranean endogenous stems, as Sarsaparilla, presents a circle of vascular wedges, resembling in appearance the stem of certain exogens; and the false bark of some aerial endogenous stems. as Testudinaria, becomes much thickened by the formation of cellular matter resembling cork.

c. Acrogenous Stem, or the Stem of Acotyledonous Plants.

This stem, in its complete development, is seen in the Tree-ferns of foreign countries. It resembles the Endo-genous stem in being unbranched, and in producing a crown of leaves at its summit. The Tree-fern form gives a peculiar aspect to the vegetation of the countries in which it occurs. The structure of the stem, which is called a caudex, consists of cells and vessels, arranged in a peculiar manner. The vascular bundles are formed simultaneously. They consist of woody tissue, often of a dark colour, surrounding a paler layer of vessels, chiefly scalariform, and dotted. The bundles assume various shapes, giving rise to the zig-zag appearance, presented in a transverse section, as seen in Figure 87. The bases of these leaves (or fronds as they are called) by their union form the stem, which is increased by additions to the summit; hence the name given of Acrogens, or summit-growers. The growing point is carried upwards by the leaves, and when once formed the stem increases very little in diameter. It is often hollow by the rupture of the internal cellular portion. On its outside the scars of the leaves remain (Fig. 88), with the markings of the vascular bundles. These bundles follow a course similar to that of the woody tissue of the liber of Exogens. The stem of Tree-ferns, then, is of moderate diameter, and does not produce lateral buds. Sometimes it terminates in two buds, which, by their growth, produce a forked stem. In the stems of the ordinary ferns of this country the acro-

genous structure is seen, although they seldom attain any height, but usually creep along the ground, forming rhizomes.

Fig. 87. The acrogenous stem occurs in Horsetails, in Clubmosses, and in true Mosses, but in these plants it does not exhibit the same marked characters as in the permanent woody stems of Ferns. Many acotyledonous plants produce stems which consist entirely of cellular tissue without any admixture of woody fibre or vessels. Such stems are either aerial or subterranean. They often present a flattened expansion or thallus lying on the surface of the Sometimes these cellular stems float in water, as in the case of Sea-weeds; at other times they creep under ground, or among the tissues of other plants, as in the case of Fungi. The spawn (mycelium) of Fungi is a sort of cellular creeping stem, which insinuates itself among the dead tissues of plants and other decaying substances. The cellular stalk of some Thallogens occasionally presents, on a transverse section, an appearance like that of an Exogenous stem. Thus Lessonia fuscescens, a species of sea-weed, has stems which are often five to ten feet long, and as thick as the human thigh, and which show concentric elliptic cellular rings. Such is also the case with Usnea melaxantha, a tree-like lichen. In these plants, however, the structure is entirely cellular, and quite distinct from that of Exogenous plants.

III. THE LEAVES AND THEIR MODIFICATIONS.

Leaves proceed from the nodes of the axis, and commence as cellular processes at the extremities of the medullary rays. In the progress of development the cells multiply, vessels are produced which ramify in the form of veins, chlorophyll is elaborated, and the foliar or leaf organs are thus completed. These organs usually spread horizontally, so as to expose one surface to the sky and the other to the earth—the surfaces differing in appearance and structure. In some plants, as Alstræmerias, the leaf is twisted naturally upon itself, so that what should be the under surface becomes the upper. Erect or vertical leaves occur, in which both sides are equally exposed to light. In some New Holland plants the leaf-organs present their edges to the earth and sky.

1. Arrangement of Leaves on the Axis.

The mode of arrangement of leaves on the stem has been denominated Phyllotaxis (φύλλον, a leaf, and τάξις, order). It is regulated by certain definite laws, and depends on the development of the nodes and internodes of the stem and branches. When the internodes are so short that the stem is apparently wanting, the leaves are denominated Radical, *Pl.CXXIV as in the Cowslip, and in the Dandelion.* In such cases

there is often at first sight some difficulty in determining Botany. the leaf-arrangement. When the internodes are elongated, and the nodes thus separated from each other, then the phyllotaxis is easily seen.

Each node is capable of producing a leaf or leaf-bud. When each of the nodes on an elongated axis produces a single leaf, the leaves are said to be Alternate (Fig. 89), because they are placed alternately on different sides of the axis. When two leaves are produced at a node, they are called Opposite (Fig. 90), because they are situated on opposite sides of the axis; while the production of three or more leaves at a node gives origin to a circle or whorl of leaves, which are then said to be Verticillate (Fig. 91).

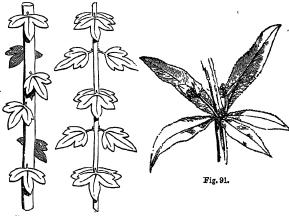

Fig. 89. Fig. 90. Fig. 89. Fig. 90.

Fig. 89. A stem with alternate leaves, arranged in a Pentastichous or Quincuncial manner. The sixth leaf is directly above the first, and commences the second cycle. The fraction expressing the divergence of the leaves is two-fifths.

... 90. A stem with opposite leaves. The pairs are placed at right angles alternately, or in what is called a decussate manner. In the lowest pair one leaf is in front, and the other at the back; in the second pair the leaves are placed laterally, and so on.

... 91. Verticillate or whorled leaves of a species of Madder. There are five leaves in the verticil or whorl.

Alternate Leaves.—This arrangement is a very common one, occurring generally in Monocotyledons, and also being frequent among Dicotyledons.* The simplest arrangement *P1. CXV. is that in which the third leaf is placed directly above the fig. 2. first, while the second is placed on the opposite side of the stem, separated by half the circumference of the circle. In this case there are two rows of leaves, one on each side of the stem, and the arrangement is said to be Distichous (dis, twice, and origos, a row). When the fourth leaf is above the first, on the same principle of the leaves being placed at equal distances on the axis, the arrangement will be *Tristichous*, or in three rows, each leaf being separated from that next to it by one-third of the circumference of the circle. If the fifth leaf is placed above the first, the arrangement will be Tetrastichous, or in four rows; if the sixth leaf, Pentastichous, or in five rows. The last-mentioned arrangement is delineated in Figure 92, which represents the branch of an oak with six alternate leaves, the sixth being placed vertically over the first.

It will be observed that, in following the course of the alternate leaves on the stem, we proceed in a spiral or screwlike manner, and that the termination of the spiral cycle is to be found in the leaf directly above that from which we commenced. On reaching it the cycle begins again, and goes through the same course as regards the number and arrangement of the leaves. Thus, in Figure 92, the cycle ends at the sixth leaf, which, in fact, commences the new spiral coil. In completing this spiral cycle we may make a single turn round the stem, as in distichous leaves, or we may make two or more. Thus, in the pentastichous cycle we make two turns round the stem, and encounter five leaves besides the first (Figs. 89 and 92). The arrangement has, therefore, been marked by a fraction, of which the nu-

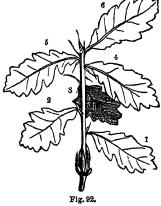

Botany. merator indicates the number of turns round the stem, and

the denominator the number of leaves in the cycle. This fraction at the same time gives the angular divergence of the leaves, or their distance from each other, expressed in parts of the circumference of the circle. Thus the fraction 1 indicates distichous leaves, where the angular divergence is one-half of the circumference of the circle, or 180° ; the fraction $\frac{1}{3}$ implies tristichous leaves, where the angular divergence is one-third of the circumference of the circle, or 120°; the fraction 2 applies to the Pentastichous or Quincuncial

Branch of Oak (Quercus pedunculata), showing the Pentastichous or Quincuncial

Branch of Oak (Quercus pedunculata), showing the Pentastichous or Quincuncial

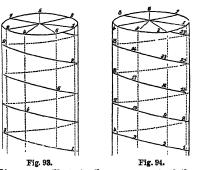

Branch of Oak (Quercus pedunculata), showing the Pentastichous or Quincuncial

arrangement (Fig. 89), a very common one among Exogens, in which the sixth leaf is immediately over the first, and two turns of the circumference are made before coming to it, the angular divergence being 144°.

The alternate phyllotaxis, and the angular divergence of leaves is explained more fully by Figures 93 and 94. In these it is shown that, in the case of alternate leaves, perpendicular lines may be drawn through the leaves placed directly over each other, and that the number of these lines indicates

the number of leaves in each spiral cycle, or the number of leaves between any leaf on the stem and that directly above it. In both these Figures it will be seen that the number of these lines is seven, and this, consequently, is the number of cycle. It is, there-

leaves in each Diagrams to illustrate the arrangement of the cycle. It is, there-consists of seven leaves.

fore, a Heptastichous cycle, ending with the eighth leaf which commences the new spiral coil. But it will also be noticed that the number of turns made round the stem in completing the cycle is different. Thus, in Figure 93, commencing with leaf No. 1, we reach leaf No. 8, or that directly above 1, after making three turns round the stem, and the fraction indicating this is 3; whereas, in Figure 94 we reach No. 8 after one turn, and the fraction, therefore, is 1. These fractions mark the angular divergence between any two leaves of the cycle, as represented in the divided circles at the upper part of the stems. In Figure 93, between 1 and 2 the angular divergence is obviously ? of a circle, or ? of 360° = 1544°, while in Figure 94 the divergence is 7 of the circle, or $\frac{1}{7}$ of $360^{\circ} = 513^{\circ}$.

Among the common arrangements of leaves may be noted, $\frac{1}{2}$, $\frac{1}{3}$, $\frac{2}{5}$, $\frac{3}{8}$, $\frac{1}{13}$, $\frac{1}{3}$, $\frac{1}{3}$, and $\frac{2}{3}$. On looking at these fractions, it will be seen that they bear a constant relation to each other, for the numerator of each fraction is equal to the sum of the numerators of the two preceding fractions, while the denominator is the sum of the two preceding denominators; and the numerator of each is likewise the denominator of the next but one preceding. In the case of stems with marked internodes, with few leaves in the cycle, and with the points of insertion small, these arrangements can

be easily detected; but when the internodes are much short- Botany. ened, and the leaves are very numerous, it is difficult to trace the arrangement.

There is thus a general tendency to alternation in the foliar arrangements of plants, and when they grow regularly the law of phyllotaxis can be ascertained correctly The arrangement, however, is often much altered by interruption in growth, and other causes, so that we cannot in all cases detect its normal condition. The Phyllotaxis is uniform in the same species, but it frequently varies in species of the same genus. Thus, in the European Larch it is $\frac{3}{2}$, while in the American Larch it is $\frac{3}{2}$. The spirals proceed either to the right or to the left. The phyllotaxis of the branches is usually the same as that of the axis, and it is then called homodromous (δμός, similar, and δρόμος, course); but sometimes it is different, and called heterodromous (ετερος, diverse).

In typical arrangements, such as those noticed, there are always certain leaves placed directly over others in a straight series, the angle of divergence dividing the circumference into an exact number of equal parts. Such leaves are Rectiserial, and are considered as being normal. Cases, however, occur, in which the angle of divergence is such, that it is not possible to divide the circumference by means of it an exact number of times, and hence no leaf can be exactly placed above another. Such cases are called by Bravais Curviserial, being disposed in an infinite curve, and hence

incapable of being placed in straight rows.

Opposite and Verticillate Leaves.—In these arrangements two or more leaves are given off at a node. There is here also a tendency to alternation and spiral arrangement as regards the pairs and whorls. Thus, in Opposite leaves, the second pair is not directly above the first, but is placed either at right angles (Fig. 90), and then called Decussate, as in the Mint tribe; or slightly to one side, so that the third, or some higher pair of leaves, is that which is superimposed over the pair with which we commence, as in the Box and in Purging Flax.* In Verticillate leaves, as in Galium and *PI CXV. Madder, those of the second whorl are not directly, over those fig. 1. of the first whorl, but are so situated as to be above the in-

tervals between the leaves of the lower whorl.

The arrangement of the leaves furnishes characters in some families of plants. Thus, the Cinchona-bark tribe have opposite leaves; the Borage tribe alternate; Labiate plants, opposite and decussate; the Madder tribe, verticillate or whorled. The arrangement of the leaves, however, is not always constant, and we occasionally meet with alternate and opposite leaves in the same plant. In some instances this anomaly may be traced to a non-development of the internodes, by which two or more single-leaved (unifoliar) nodes are brought together. Thus, in Rhododendron ponticum, the alternate leaves, by such an arrestment, are sometimes seen almost verticillate. Again, in such plants as the Larch, Cedar, and Pine, the arrestment of the internodes, according to a certain natural law in their development, gives rise to clustered or fascicled leaves.

In the embryo state of dicotyledons, the leaves or cotyledons are opposite; while in monocotyledons the production of one leaf at the node shows the tendency to alternation. The early cotyledonary leaves are called Seminal; those afterwards produced, and constituting the ordinary leaves, are called Primordial. Leaves inserted on a shortened stem close to the ground, have been already noticed as Radical, those on the main axis are Cauline, on the branches, Ramal, and on the flowering stalks, Floral.

Vernation, or Præfoliation.—These names are applied to the arrangement of the leaves in the leaf-bud, and include both the mode in which each leaf is folded, and the relation which the leaves bear to each other. The leaf-bud is produced in the angle where a leaf joins the stem; it contains the growing point of the stem or branch, with its leaves and

Botany. certain protective appendages called scales, tegmenta or perulæ. These scales or outer leaves are often of a coarse nature, covered with resinous matter, and arranged differently from the leaves in the interior, as may be seen in the common Sycamore.

The individual leaves in the bud are folded and rolled up

in different ways. When the leaf is folded from its midrib, so that its halves are applied with their upper surfaces towards each other, as in Fig. 95.

Fig. 96. Fig. 97. the Oak and Fig. 95. Transverse section of a conduplicate leaf.

Magnolia, it is ... 97. Transverse section of a plicate or plaited leaf.

Conduplicate (Fig 95); when the apex is bent towards the base, as in the Tulip-tree, it is Reclinate, or Inflexed; when folded like a fan, as in the Maple and Vine, the leaf is Plaited, or plicate (Fig. 96); when the leaf has each of its edges rolled inwards towards the midrib, as in the Violet and Water-Lily, the vernation is *Involute* (Fig. 97); when outwards, as in Rosemary and Azalea, Revolute (Fig. 98);

when the leaf is rolled from one edge into a single coil, with the other edge exterior, as in the Apricot and Plantain, is Convolute (Fig. when

rolled from apex to base like a crosier, as in Ferns and Sundew, it is Circinate (Fig. 100).

The relative position of the leaves in the bud gives origin to the following terms:—Valvate, when leaves are placed in a circle, so as to touch each other at their edges only, without overlapping; Imbricate, when the outer leaves successively overlap the inner to a greater or less extent (Fig 101).

These kinds of vernation occasionally become Twisted or Contortive. When involute leaves are applied

Fig. 101. Fig. 102. are applied in a circle
without
overlapping the vernation, is Induplicate;

when conduplicate leaves successively embrace each other, as at the base of the Iris, they are equitant (Fig 102); and when the half of one conduplicate leaf covers half of another, the term Half-equitant or Obvolute is applied (Fig. 103); when a convolute leaf incloses another which is rolled up in a similar manner, the vernation is Supervolute (Fig. 104).

2. Anatomy or Structure of Leaves.

The leaf consists of a cellular and vascular portion; the former constituting the Parenchyma—the latter the Ribs and Veins. The whole is covered by an integument. The flat expanded portion is called the Lamina, blade or limb (Fig. 105, *l*), consisting of cells traversed by vessels, and the narrow portion is called the *Petiole*, or leaf-stalk (Fig. 105, p), in which the cellular tissue is less abundant, and the vessels are more closely united. At the base of the petiole there

are sometimes certain leafy appendages denominated Stipules Botany.

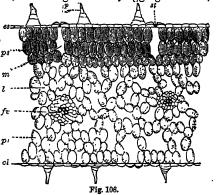

(Fig. 105, s). The petiole is sometimes wanting, and the leaf is then Sessile; at other times the blade is transformed, so as to appear like a petiole. The leaf may be denominated a flattened expansion of the green layer of the bark, strengthened by woody fibres and vessels. The Parenchyma varies much in its extent, and in the form of its cells. In fleshy leaves it is abundant, and its cells are loose, and more or less rounded. In an ordione of which (the upper) is exposed to the light. The epidermis covering these surfaces consists of compressed colourless cells. The telling transfer of the penole, p. The lamma or blade is marked to the penole, p.

compressed colourless cells. That of the lower surface is often of a paler colour, and is provided with stomata and hairs; while on the upper side the epidermis is more tough and dense, and is either entirely destitute of stomata, or possesses them in small number. In leaves placed vertically, the stomata sometimes exist in equal number on both sides: in floating plants, as Water-Lilies, the stomata exist only on the upper surface of the leaf; while in submerged leaves no stomata occur on either surface, and the true epidermal layer of cells is absent. De Mercklin states, that leaves have their origin in cellular papillæ arising from the axis. Their apex is the first part formed, and it is pushed forward by the growth of the part below. The leaf-stalk is formed after the blade, the lower part of it being the last developed. Leaves are undivided in their early state; all the divisions which take place in them are subsequent formations. The mode in which the parenchyma increases, and the arrangement of the veins, give to the leaves their varied forms.

Parenchyma.—In ordinary leaves, this consists of two distinct layers of cells, one connected with the upper surface (looking to the sky), and consisting of compact oblong cells, placed endwise (Fig. 106, ps); the other, connected with the lower side, consisting of loosely-aggregated cells,

having numerous cavities between them (Fig. 106, pi), and, when of an elongated ps form, placed with their long diameter parallel to the $^{\it l}$ epidermis. The cavernous nature of the lower epidermis seems to p be connected in some degree with the stomata and their functions. The cells on the upper side are usually placed close to each other, without any space be-

Section of a Melon-leaf, perpendicular to the surface; cs, upper epidermis; ct, lower epidermis; p, hans; st, stomata: ps, upper layers of parenchymatous cells; ps, lower layers of parenchymatous cells; ps, lower layers of parenchymatous cells; ps, meatus, or canalis connected with stomata; they are sometimes called hypostomatic spaces; t, lacune, or cavities between the loose cells in the cavernous lower parenchyma; fs, bundles of fibro-vascular tissue, consisting of woody, dotted, spiral, and other vessels.

tween them, except in cases where stomata occur (Fig. 106, st). Sometimes there are several layers of epidermal cells, more particularly in plants exposed to the heat of the tropical sun, as the Oleander. The parenchyma is occasionally deficient at some parts of leaves, giving rise to deep indentations or to perforations. In Monstera pertusa there are distinct holes in the leaves; and in an aquatic plant of South Africa (Ouvirandra fenestralis) the tissue of the leaf-

is made up of interlacing filamentous cells, with perforations between them, giving the appearance of a skeleton leaf. In Victoria regia there are peculiar perforations in the leaves. The surface of leaves is sometimes smooth (glabrous), at other times hairy (hirsute), downy (pubescent), or woolly. The hairs are either lymphatic or glandular. In the case of the Sundews (Drosera) the leaves are fringed with glandular hairs (ciliated), and their surface is covered with them

(Fig. 107); while in Venus's Fly-Trap (Dionæa muscipula) there are irritable hairs on the leaves, which, when touched, cause the two sides of the leaf to fold together.

Vascular system.—This consists of a double layer of vessels which may be separated by maceration. It is composed of woody, laticiferous, dotted, and various kinds of spiral vessels. These vessels collectively form the petiole or stalk of the leaf, and spread out in the lamina or blade, so as to constitute the veins. When a leaf is macerated, the cellular tissue is separated, and the vascular bundles alone remain. In some leaves, as in the Barberry, the vessels forming the veins are hardened, producing spines without any parenchyma. The hardening of the extremities of the vascular hairs.

tissue is the cause of the spiny margin of many leaves, such as the Holly, of the sharp-pointed leaves of Madder, and of mucronate leaves, or those having a blunt end with a

hard projection in the centre.

The firm and prominent bundles of vessels in the leaf are called Ribs po (costæ), and others less conspicuous are denominated Veins. The term Nerve, as applied to the vessels of the leaf, is now generally given up to avoid ambiguity as to function. In (Fig. 108) there is given a representation of a vertical section of a branch, showing the mode in which the vascular bundle, fv, gives off a prolongation to the leaf-stalk, f. The vessels pass from the sheath surrounding pc the pith, m, through the parenchyma, pc pc, and communicate with the young bud, b, in the axil of the leaf.

Venation.—This term has reference to the arrangement of the vascular tissue of the leaf. There are two marked forms of venation, one in which the vessels from the petiole or stem, on entering the leaf, are continued in the form of one or more ribs, which give off branches on either side, and form an anastomeois or network of vessels (Fig. 109): the other in mosis or net-work of vessels (Fig. 109); the other, in

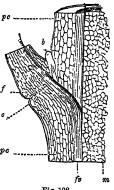

Fig. 108.

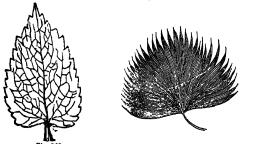

Fig. 109. Fig. 110

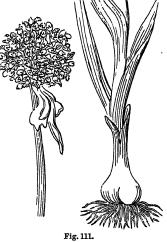

Fig. 109. Leaf of Dead-nettle (Lomium), showing retriculated venation.

... 110. Leaf of Fan-Palm (Ohamarops), showing the veins running from the base to the margin, and not forming an angular net-work. which the vessels, when entering the leaf, divide into several

veins or ribs, which run more or less parallel to each other, Botany. and are united by simple transverse veins, as in Palms (Fig. 110), grasses, and the leek (Fig. 111); or in which the midrib gives off lateral veins which run parallel, as in the Banana (Fig. 86). The former are Reticulated or Netted leaves, and

are common in dicotyledons, while the latter are Parallel-veined, and are characteristic of monocotyledons.

In reticulated leaves there is either one primary rib called *Midrib*, or there are several prominent ribs, as in Cinnamon. When a single midrib is present it gives off branches or veins. which either proceed directly to the margin, as in the Feather-veined leaves of the Oak (Fig. 92) and Chestnut, or which end within the margin in curved veins, as in Lilac and Dead-

nettle (Fig. 109); in Leek (Allium Porrum), with parallel-veined the latter case, marginal sheathing leaves proceeding from a bulb.

veinlets proceed from the curved veins. When there are three prominent ribs, as in Cinnamon, the leaf is Tricostate; when five, Quinquecostate. When the midrib gives off two ribs a little above the base, the leaf becomes Triplicostate; when it gives off five, Quintuplicostate.

In a many-ribbed leaf, the ribs may converge towards the apex, as in Cinnamon, or they may diverge. In the latter case they are said to radiate, and they give origin to Palmate and Palmatifid leaves, as in the Sycamore. Parallel-veined leaves have either a single midrib, the veins from which come off in a parallel manner, and run to the margin without forming a net-work, as in the Banana (Fig. 86), and Indian Shot (Canna); or they have numerous veins or ribs running from base to apex (Fig. 111), converging as in Grasses and Lilies; or diverging, as in Palms (Fig. 110).

In very succulent plants, as the American Aloe (Agave americana), and Fig-Marigolds, where the parenchyma abounds, the veins are obscure, and in plants such as Mosses and Sea-weeds, the so-called veins are composed of an aggregation of long cells, without any woody fibre. In many plants belonging to the Myrtle order (Myrtaceæ), which have ribbed leaves, there is an obscure vein which runs from the base to the apex of the leaf, close to the margin, and in which the lateral veinlets end. The primary veins come off from the midribs of leaves at different angles, and thus contribute to give form to the leaf. Primary veins coming off at a very acute angle, and converging, give rise to narrow leaves; those proceeding more at a right angle frequently produce broad leaves; while those coming off at obtuse angles cause prolongations at the base of the leaf. So also with veins radiating from a point, their greater or less divergence gives origin to leaves of a broader or a narrower form.

The arrangement and form of the foliaceous appendages of plants depend much on the number, the development, and the relation of the fibro-vascular bundles of the stem. In vascular plants the skeleton of the leaf is formed by an expansion of the fibro-vascular bundles of the stem. The leaves contain vessels similar to those forming the bundles at the point where they escape from the axis. The vascular bundles, as well as the parenchyma of the stem, expand in the leaf in various ways.

M'Cosh thinks that the venation of leaves bears an ana-

fig 1.

Botany. logy to the distribution of the branches, so that the leaf and its veins represent the stem and branches of the plant. He considers that in plants there are three homotypal parts, morphologically allied, and representatives of each other, viz., the root and its ramifications, the stem and its branches, and the leaf with its veins. These parts he looks upon as typically analogous. He has carried out his researches chiefly in regard to reticulated leaves. The angles at which the veins are given off, he considers as being the same as those at which the branches come off, and he has attempted to prove this position by numerous measurements of angles. In trees there is a certain normal angle at which branches are given off, producing a peculiar physiognomic effect. This angle may be much modified by circumstances, and it may vary according to the age of the branches. The determination of this angle is a point to which M'Cosh calls attention, and his researches lead him to adopt the view that the same angle will be found to prevail in the leafformation.

3. Conformation of Leaves.

With few exceptions, every plant has leaves at some

period of its growth. Even those which produce leafless stems have generally seed-leaves (Cotyledons) in their *Pl. CXXV. embryo state. The Dodders* and a few other plants, are exceptions to this rule. Leaves present various forms, from the scales of Broomrapes, and the linear leaves of Asparagus and Pines, up to the large foliar expansions of the Banana, and of the Talipot Palm. To the nature of the venation and the development of parenchyma all the leafy forms must be traced. Leaves are usually arranged under the heads of Simple and Compound; the former having a blade composed of one piece, and having no articulation beyond

Fig. 112.

the point where they join the stem, as in the Oak (Fig. 92); the latter having a blade divided into separate pieces or leaflets, which are articulated with the petiole (Fig. 112.)

Simple Leaves.—These, although formed of one piece,

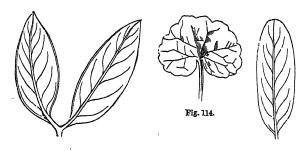

Fig. 113. Ovate-lanceolate leaves of a species of Senna. The leaves are oblique at the base and acute at the apex.

... 114. Leaf of Ground Ivy (Nepeta Glechoma), having a kidney-like form, and hence called reniform. Its margin is crenate.

... 115. Oblong leaf of a species of Senna. The apex is obtuse, and the base obligne.

may have their blades variously divided, provided the se-VOL. V.

parate portions are not supported on stalks, nor articulated Botany. to the petiole, nor to the midrib. In their very young state they are entire or undivided, and equally developed. When they increase more on one side than on the other, they become either oblique, as in the Begonia and Lime (Fig. 105), or slightly unequal at the base, as in Senna (Fig. 125); and when the cells and vessels increase and elongate only at certain points, divisions take place in the margin of the leaves, and in the substance of their laminæ.

In the circumscription or margin of the leaf, the following varieties occur:—*Entire*, without any divisions (Fig. 113); *Crenate*, with superficial rounded divisions (Fig. 114); Serrate, with acute points, arranged like the teeth of a saw (Fig. 109); Dentate, with similar pointed projections,

not arranged in a saw-like manner;* Repand and Undulated, *Pl.CXXII

when the margin is wavy and sinuous, or, as it is often called, crisp, as in curled leaves; sometimes, as in the Holly, the leaf is undulated, with spiny teeth. When the apex of a leaf is blunt and rounded, it is called Obtuse (Fig. 115); when sharp, and forming an acute angle, it is Acute (Fig. 113). The apex is Abrupt or Truncate, when it is terminated by a straight transverse line, as in the Tulip tree; Rerounded and

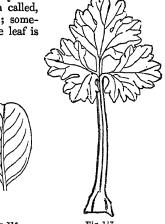

Fig. 117. Fig. 116. tuse, when it is Fig. 116. Emarginate leaf of a species of Senna. The leaf in its contour is somewhat obovate, or rounded and inversely egg-shaped, and its base is ob-

rounded and slightly depressed; ... 117. Tripartite leaf of Ranunculus. Each of the segments is lobed, and toothed at the margin. The petuole is dilated at the base. Venation radiating.

ciency or notch at the apex (Fig. 116); Obcordate, when the deficiency is very evident, and the lobes large, so as to resemble an inverted heart on cards. When the apex is drawn out into a long point, as in Ficus religiosa, the leaf is Acuminate or pointed; when the apex is blunt, and presents a stiff hard point, it is Mucronate.

When the substance of the lamina is divided to about the middle, the terms *Cleft* (in composition fid) and *Lobed* are applied; and when the division extends to near the base or midrib, the term Partite is used. These divisions, occur-

ring in a radiating-veined leaf, give origin to the terms, bifid (twice cleft), trifid (thrice cleft), quinquefid (five-cleft), and multifid (many-cleft); also to the terms bilobate (two-lobed), trilobate (threelobed), &c., when the divided portions of the leaf are large; and tripartite (Fig. 117), quinquepartite (Fig. 118), and multipartite, when the divisions extend to the base;

Palmate (like the palm of the hand), when there is a broad leaf is sometimes called palmi-partite, palmately-partite, or dissected. The venation is radiating, and the leaf are cuneate, and as in some species of Passionflower; Palmatifid, or Pal-

each of them is cleft and toothed at the apex.

mately-cleft, when the divisions are more than five, as in Castor oil (Fig. 119). The terms palmate and palmatifid are, however, often used indiscriminately to mark a leaf Fig. 1.

Botany. having a broad portion like the palm of the hand, and ferent parts determine in a great measure the contour of the Botany. either five or more lobes.* When the parts of a palmatifid *Pl. CXIV. leaf are narrow, like the fingers, the term digitilobed,

*Pl. CXIII. digitipartite, * and dissected, are applied; and when they are cut into thread - like divisions, as in the submerged leaves of Ranunculus aquatilis, they are said to be filiformly dissected. The term Pedate (like the foot of a bird) is applied when the lateral divisions of a three-lobed leaf are again divided, as in stinking Helle-* Pl. CX. bore* (Fig. 120).

Fig. 119.

Leaf of Castor-oil plant (Ricinus communis). It is palmately-eleft, and exhibits seven lobes at the margn. The petuole is inserted a little above the base, and hence the leaf is called peltate or shield-like. In a feather-veined leaf similar divisions give origin to the

terms Pinnatifid, with large lateral divisions, as in the Oak

(Fig. 92); Pectinate (comb-like), with very narrow divisions; Pinnatipartite, when the divisions extend near to the midrib (Fig. 121); Pinnately-divided, when the divisions extend to the midrib. When the primary divisions of

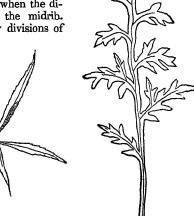

Fig. 120.

Fig. 121.

Fig. 120. Pedate leaf of stinking Hellebore (Helleborus fætidus). The venation is radiating. It is a palmately-partite leaf, in which the lateral lobes are deeply divided. When the leaf hangs down it resembles the foot of a bird, and hence the name.

... 121. Pinnatipartite leaf of a species of Poppy. The leaf is feather veined, and the divisions take place laterally to near the midrib. The segments are pinnatifid, and pinnatipartite. The leaf may be called bipinnatipartite.

such leaves are again subdivided in a similar way, the terms bipinnatifid and bipinnatipartite (Fig. 121) are applied; and when not only the primary, but also the secondary segments are divided in a similar way, the terms tripinnatifid and tripinnatipartite are used. In a pinnatifid leaf it sometimes happens that there are few divisions, in consequence of the lobes at the apex or base being united, thus giving rise to the Lyrate leaf (like an ancient lyre), with a large terminal lube, and segments becoming smaller as they approach the petiole (Fig. 122); and the Panduriform, when the lobes have a recess or sinus between them, so as to make the leaf resemble a violin. When the divisions of a lyratelypinnatifid leaf have acute terminations, and point downwards, as in the Dandelion, the term Runcinate is applied (Fig. 123).

In the case of reticulated leaves, the angle which the veins form with the midrib, and their comparative lengths in dif-

leaf. The following are some of the usual terms employed: -Linear, when the leaf is narrow, and the veins proceed-

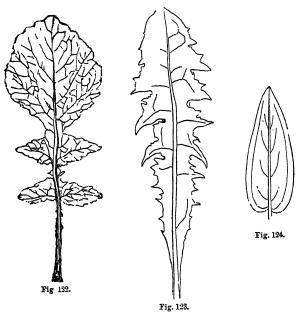

Fig. 122. Lyrate leaf of Turnip (Brassica Rapa). It is a simple leaf with reticulated venation, in which the terminal lobes are united, so as to make the leaf resemble an ancientlyre. When the lateral divisions of such a leaf become leaflets articulated to the petuole, then the leaf is compound, and is said to be lyrately-pinnate.

123. Runcinate leaf of Dandelion (Leontodon Tarazacum). It is a pinnatifid leaf, with the divisions pointing towards the petiole.

124. Ovate acute leaf of Coriaria myrtifolia, one of the adulterations of Senna. Besides the midrip there are two intramarginal ribs which converge to the apex. The leaf is therefore tricostate.

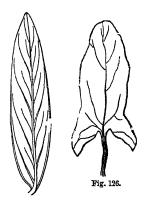

ing from the midrib are very short, and nearly equal. When linear leaves are sharp-pointed, as in Pines and Juniper, they are called Acerose; when linear leaves taper, so as to be like an awl, they are called Subulate; leaves are Oblong, when the veins from the midrib are longer than in linear leaves but still nearly equal, and the apex is rounded (Fig. 115); Rounded and Elliptical, when the veins from the centre of the midrib are longest, and the forms approach more or less to the circle or ellipse.

When the veins coming off from near the base are the longest, and the leaf has the shape of an egg, it is called Ovate (Fig. 124); it is Obovate (inversely egg-shaped) when the veins at the apex are longest, and the leaf is thus like an ovate one reversed (Fig. 116); when the apex of an obovate

heart on cards, the leaf is Cordate (Figs. 105 and 109); it

leaf is straight, or not uniformly rounded, it becomes Cuneiform (wedge-shaped); when an obovate leaf, with a round apex, tapers to the base, as in the Daisy, it is called Spathulate; a leaf is Lanceolate (Fig. 125) when the veins near the base are longer than those above and below, and the leaf tapers towards the apex; Ovato-lanceolate, when the general form is lanceolate, but the base is broad (Fig. 113).

When the lower veins come off at an obtuse angle from the midrib, and are curved back so as to form with the parenchyma two large round lobes at the base, with a nar-like the see. ... 126. Sagittate leaf of a species of convolvulus.

* Plate CXXXV. fig. 1.

Botany. is Reniform when the recess is large, and the contour stalklets of their own, or are sessile. Compound leaves may Botany. rounded, so that the leaf resembles a kidney (Fig. 114); Sagittate, when the lobes of a cordiform leaf are acute, so as to resemble the head of an arrow, as in species of Convolvulus (Fig. 126), and Arum;* Hastate, when the lower veins proceed nearly at right angles, and form two lateral narrow lobes, as in Rumex Acetosella (Fig. 127); Auriculate, when the lobes at the base of a hastate leaf are separated from the lamina, so as to be distinct segments; Deltoid-hastate, when a hastate leaf is short, and resembles the Greek letter delta, as in Ivy. Sometimes a leaf cordate at the base (next the petiole), has a rounded contour, and it becomes Rotundatocordate (Fig. 128, a).

The lobes at the base of leaves are sometimes united more or less completely, thus giving rise to the Peltate or Shieldlike form, as in the Indian Cress (Fig. 128, b), and Castor

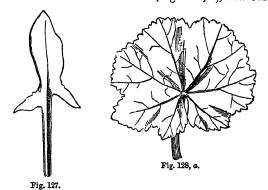

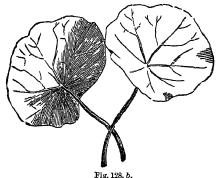

Fig. 127. Hastate (Halbert-shaped) leaf of Sheep's sorrel (Rumez Acetosella).

The lobes at the base are in this specimen unequal.

128. a. Rounded leaf of Mallow (Malva rotundifolia). It is cordate at the base, and is hence called rotundato-cordate. The margin is toothed and crenate.

oil (Fig. 119); and the Orbicular form, when the petiole is

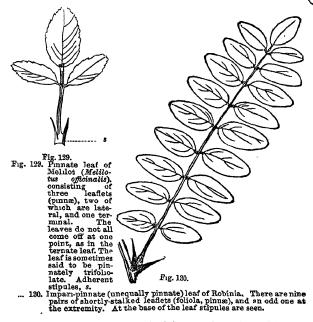

attached in the centre of a large rounded leaf, as in Pennywort (Hydrocotyle vulgaris) and Victoria regia. Very succulent leaves, with obscure veins, assume certain thickened forms, so as to become cylindrical, conical,

sword - shaped, Peltate (Shield-like) leaves of Indian Cress (Tropwolum and ave-shaped and axe-shaped.

Simple parallel-veined leaves usually have their margins entire, especially when the veins converge. They assume some of the forms already noticed, such as linear, oval, elliptical, oblong, and ovate. It is comparatively rare to find any marked divisions of their laminæ. When the veins diverge at the base, or come off at obtuse angles, we meet with hastate, sagittate, and cordate forms, and their various modifications. In some Palms, where the veins running in straight lines diverge, the margin of the leaf is cut into linear segments of different lengths (Fig. 110). In some Monocotyledons the leaves present a reticulated venation, and they are hence called Dictyogenous (δίκτυον, a net).

Compound Leaves.—These originate, like simple leaves, in the form of undivided cellular projections from the axis. When fully formed, they consist of laminæ divided down to the petiole or midrib into distinct pieces or leaflets, which are articulated, more or less distinctly, to the common stalk (Fig. 129). These leaflets (foliola) are either supported on

be reduced to two well-marked forms; those formed by the divisions of a feather-veined unicostate leaf, and including the various pinnate forms (Fig. 130); and those traced to

the division of a radiating-veined multicostate leaf, including the various digitate forms (Fig.

When there is a distinct midrib giving off primary veins laterally, which are covered with parenchyma in such a way as to form separate articulated leaflets, the leaf is Pinnate, as seen in Figure 130, which represents a compound leaf composed of nine pairs (juga), of shortly petiolated pinnæ, and an odd leaflet at the end.

If a pinnate leaf ends in septenate leaf of the Horse-chestnut (Escura pair of leaflets, the extremity of the midrib digitate.

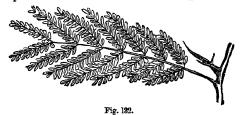

Fig. 131.

being either leafless or ending in a tendril or point, the leaf is said to be Equally or Abruptly-pinnate (pari-pinnate). When there is a leaflet at the point, the leaf is said to be Unequally-pinnate (impari-pinnate), as in Figure 130. When a lyrate leaf becomes truly pinnate, i. e., has its divisions articulated to the midrib, it is Lyrately-pinnate; and when the leaflets of a pinnate leaf are of different sizes, the term Interruptedly-pinnate is applied. Some parallel-veined leaves, as those of the Coco-nut, Date, and Sago Palms, are pinnate.

The number of pairs (juga) of leaflets in a pinnate leaf varies. There may be only three leaflets (Fig. 129), in which case two are lateral, and one is terminal. Such a leaf approaches to the ternate leaf which belongs to the radiating venation, and is distinguished by the distance intervening between the two articulated lateral pinnæ and the terminal one. When the leaflets of a pinnate leaf are divided into separate pieces or pinnules, the leaf becomes Bipinnate (twice pinnate), as in Figure 132. When the subdivision takes place

Botany. to a further extent, the leaf becomes either *Tripinnate* or *Decompound*.

Compound leaves referred to the radiating venation, i. e.,

Bipinnate (doubly pinnate, twice pinnate), leaf of Gleditschia triacanthos. Each of the primary pinnas is divided into small leaflets. It may be said to be a pinnate leaf, with the leaflets slee pinnate.

multicostate with diverging ribs, are distinguished from those referred to the feather-venation, by the leaflets coming off from one point. When the leaflets coming from one point are two, the leaf is Binate or Unijugate (one pair); when three, Ternate or Trifoliolate, as in Woodsorrel and Strawberry; when five, Quinate or Quinquefoliolate, as in Hemp; when seven, Septenate or Septemfoliolate, as in the Horsechestnut (Fig. 131). When the leaflets are five, the leaf is often called Digitate. Similar forms may occur among pinnate leaves (Fig. 129), but in them the leaflets will be seen not to come off from the point of the petiole, but at certain distances from each other. In the case of a ternate leaf, the two lateral leaflets may disappear, while the central one remains articulated to the petiole. Some consider this as being the case in the Orange leaf (Fig. 133), which is therefore looked upon as a compound leaf with a single jointed leaflet. A ternate (trifoliolate) leaf may divide in such a way as to form three leaflets on the secondary veins, proceeding from each of its primary veins, and thus become Biternate (doubly ternate); while a further subdivision, in a similar way, will render it Triternate (triply ternate).

4. Petiole or Leaf-Stalk.

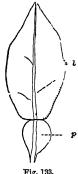

The stalk supporting the blade of the leaf is denominated the *Petrole* (Fig 105, p). It is absent in the case of sessile leaves; and, in certain instances, the distinction between the lamina and the stalk is not well defined. The petiole consists of a definite number of vascular bundles enclosed in a small amount of parenchyma. The vessels are woody, dotted, spiral, and laticiferous, and they are derived from the internal part of the stem, as shown in Figure 108, where the vessels, fv, surrounding the pith, m, are traced into the leaf-stalk, f.

At the point where the vessels leave the stem there is often a small enlargement (pulvinus), composed of cellular tissue, and an articulation or joint. When the leaf dies, it separates from the stem at the joint, leaving a mark or scar (cicatrix, cicatricula) in which the ends of the different vascular bundles are seen arranged in a definite order. The form of the scar, and the arrangement of the bundles, differ in different plants, and furnish, in some instances, distinct characters. In the case of many Palms, and of Tree-ferns, the scars left by the leaves are very conspicuous.

When there is no articulation between the petiole and the stem, as is the case with many Endogens, the leaf is continuous with the axis, and is not deciduous, but withers on the stalk. In many Liliaceous plants, the leaves during their decay continue attached to the plants. In compound leaves there is usually an articulation, where the leaflet or leaflets join the petiole. At this joint also a cellular swelling (struma) occurs. In many pinnate leaves, as those of the Sensitive plant, the axial and foliolar joints and swellings (pulvinus and struma) are very evident. Where the petiole joins the blade its vessels diverge, so as to form the ribs and veins—the vascular bundle which continues in the direction of the stalk being the midrib. The epidermis of the petiole has few stomata.

The petiole is usually either round, or half cylindrical, with a flattening or grooving on the upper surface. In the Aspen it is compressed laterally, or at right angles with the blade

and hence the trembling of its leaves from the slightest breath of air. When the leaves of a plant float in water, the petiole is sometimes distended with air cavities, as in the Water Chestnut. The edges of the petiole in plants such as the Orange (Fig. 133), the Quassia plant, Venus' Fly-trap, the Sweet Pea, and other species of Lathyrus, are bordered by a leaf-like expansion called a Wing, and hence they are denominated Winged or Bordered petioles. Such leafstalks are occasionally united to the axis for some extent, and thus become Decurrent. In many Endogens, especially grasses, the leaf-stalk forms a Sheath round the stem; this sheath in grasses terminates at the upper part, in a process called a *Ligule*, as seen in Figure 134, where g is the sheath (vagina), I the blade of the leaf, and lig the ligule. In Umbelliferous plants* the petiole is expanded, and forms a conspicuous sheath

rig. 133.

Leaf of Grange (Citrus Aurantium), showing a winged petiole, p, which is articulated to the lamina, l. It is considered a compound leaf, having only one *Pl.CXX leafer.

round the stem. This sheathing portion of the petiole is formed by the divergence of the vascular bundles on either side. The vessels thus surround the stem, and are covered with parenchyma. This petiolary sheath may be considered as a modification of stipules.

In some Australian plants belonging to the genera Acacia and Eucalyptus, the petiole is flattened, and becomes a foliar expansion, which occupies the place of true leaves. Such petioles have received the name of *Phyllodia* (φύλλον, a leaf).

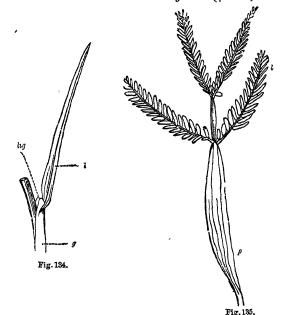

Fig. 134. Stem of a Grass (Poa) with leaf. The sheathing petiole, g ending in a process, tig, called a ligule; the blade of the leaf, l.

135. Leaf of an Acatia (Acatia hterophylla), showing a flattened leaf-like petiole, p, called a phyliodium, with straight venation, and a bipinnate lamina, l.

The trees bearing them give a peculiar character to some forests in New Holland. These phyllodia are usually placed vertically, presenting their edges to the sky and earth, and their venation is parallel. They occasionally bear pinnate or bipinnate laminæ, and in such cases they are frequently much narrowed in their dimensions. In Figure 135 a bipinnate leaf is represented, with its flattened petiole or phyllodium, the venation of which is straight. On the same tree may be seen naked and leaf-bearing phyllodia. By this, as

Fig. 136.

Botany. well as by their venation, their petiolary character is determined. Trees producing naked vertical phyllodia only have a singular effect as regards light and shade. Some shrubby species of Wood-sorrel exhibit phyllodia, which are either naked, or bear ternate leaflets.

5. Stipules or Stipulary Appendages.

Stipules are leafy appendages situated at the base of the petiole, and having normally a lateral position as respects the leaf. They have usually the same structure as leaves, and, in some instances, as in Lathyrus Aphaca, they constitute the only leaves which the plant produces. In the Pansy (Fig. 136), they are as conspicuous as the or-

dinary leaves. In the Pea, they are also large, and in many of the pea tribe they assume peculiar sagittate forms. Stipules are not present in all plants. Those having stipules are called Stipulate, those 1 without stipules are Exstipulate. At a certain stage of their growth, some stipules are larger than the leaves or leaflets produced before them. Thus they serve as a protection to the leaves in the young state, as in the India-rubber Fig, Potamogetons, Magnolias, and the Beech. These protective stipules generally fall off when the leaf expands.

The form and appearance of stipules vary; some are leaf-like, others cirrhose; some are small, others large; some assume a scaly or membranaceous appearance, others are hard and spiny; some are separated from the rate and free, others are united. In this way the nature of the stipules gives characters in many natural orders. In the Cinchons hark trees which have copperately. Cinchona bark trees, which have oppo-

site leaves, the stipules unite, so as to form one on each side of the stem between the petioles, hence they are called Internetiolar. In the Rhubarb tribe, which have alternate *PI.CXXX.leaves, the stipules unite, so as to form a sheath or Ochrea* round the stem. In the Plane tree, and in the Astragalus, they unite, so as to form a leafy expansion on the opposite side from the leaf, and in the Rose tribe they are united to each other and to the petiole, thus becoming adnate. The petioles of many plants have a sheathing portion at their base (Fig. 117), which may be considered as adherent stipules. On this account the reticulum, or mat-like substance, at the base of the leaves of palms, is often called stipular. Besides the leaves at the base of the petiole, smaller leaflets (stipels) are occasionally produced at the base of the pinnæ of compound leaves, as in the bean.

6. Transformations of Leaves and their Appendages.

Some of these transformations have been already noticed, but there are others to which it is necessary to direct attention. The morphological relations between leaves, scales, and spines—between petiole and laminæ, and between stipules and petioles, have been adverted to. All these nutritive organs are sometimes changed into tendrils (cirrhi), with the view of enabling the plants to twine round others for support. In Leguminous plants (the pea tribe) the pinnæ are frequently cirrhose. Sometimes a whole leaf becomes cirrhose, as in some species of Lathyrus. In Smilax there are two stipulary tendrils, while in the Cucumber tribe there is a single one at the base of each leaf. In the Passionflower the lateral leaf-buds, and in the Vine the terminal ones, become tendrils.

The leafy parts of plants are also liable to become hardened and spinescent. The leaves of some species of Astragalus and Barberry, and the stipules of the False Acacia

(Robinia) are spiny. In these instances the vascular bun- Botany. dles are developed in a marked degree, while the parenchyma is deficient. To the same cause is attributed the spiny margin of the Holly-leaf. In the Gooseberry, the swelling (pulvinus) at the base of the petiole, and below the leaf, assumes a spinose character.

Changes in the appearances of leaves are produced by adhesions and foldings of various kinds. When two leaves unite at their bases, as in some species of Honeysuckle (Fig. 137), they are called Connate. When the lobes at the base of a leaf unite on the opposite side of the stem

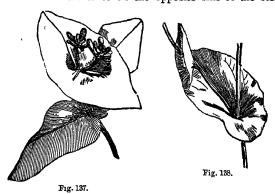

Fig. 137. Connate leaves of a species of Honeysuckle (Lonicera Caprifolium).

Two leaves are united by their bases.

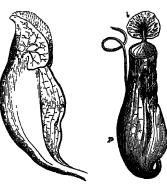

138. Perfoliate leaf of a species of Hare's-ear (Bupleurum rotundifolium).

The two lobes at the base of the leaf are united, so that the stalk appears to come through the leaf.

from the lamina, a Perfoliate leaf is the result, as seen in some species of Bupleurum (Fig. 138) and Baptisia. The formation of Peltate and Orbicular leaves has been traced to the union of the lobes of a cleft leaf. In the case of the Victoria leaf the transformation may be traced during germination; the first leaves produced by the young plant are linear, the second are sagittate and hastate, the third are rounded-cordate, and the next are orbicular. The cleft indicating the union of the lobes remains in the large leaves. Many forms of stipules, such as petiolar, interpetiolar, and sheathing, are traced to adhesion.

Folding of the leafy appendages, and union of their edges, give rise to the formation of a hollow leaf or Pitcher (ascidium, ascus). In the Side-saddle flower the ascidia are considered as being formed by the petiole or phyllode, a part of which, in an unadherent state, is prolonged upwards

Fig. 139). In the Pitcher-plant there is an evident lid, united to the pitcher by a joint (Fig. 140, l). The lid is looked upon as the metamorphosed lamina, articulated to the hollow petiole or phyllode. It may be said to resemble the jointed leaves of the Orange, or Dionæa, with their The hollow (fistu-

petioles folded so rate as to adhere by the edges, and their laminæ reduced in size, so as to form a lid (operculum).

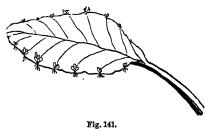

The hollow (fistu-

lar) leaves of the onion, and of other species of Allium, may

Botany. be traced to the folding and adhesion of the margins of the

It has been already remarked, that buds and bulbils are

produced at the points where leaves join the stem. In some instances, however, we find that budsare produced from the margins or surfaces of leaves. In Bryophyllum (Fig. 141), this is a company occurrence

141), this is a common occurrence,

Leaf of Bryophyllum calycinum, producing buds along the margin, at the extremities of the primary veins.

and it is met with in many plants of the order Gesneraceæthe leaves of which, when placed on the surface of moist earth, become what is called *proliferous*, or bud-bearing.

II.—PHYSIOLOGY OF THE NUTRITIVE ORGANS.

I. CHEMISTRY OF VEGETATION.—CONSTITUENTS OF PLANTS, AND SOURCES WHENCE THEY ARE DERIVED.

It is impossible to study the functions of plants without knowing their chemical composition, and the sources whence they derive the materials necessary for carrying on their vital processes. Hence, before proceeding to consider the plant in a state of activity, and as performing vital actions, it is necessary to give a general view of the Chemistry of Vegetation. This subject has engaged the attention of many distinguished chemists, among whom may be mentioned Saussure, Sprengel, Davy, Liebig, Dumas, Mulder, Boussingault, and Johnston. The subject has assumed importance in an agricultural point of view, and a knowledge of it is essential for carrying on farming operations in an enlightened manner. The theory of manures, and the practical application of them, is intimately connected with the knowledge of the composition of plants and of soils.

1. Organic Constituents of Plants.

The materials of which the substance of plants is composed are of two kinds, Organic and Inorganic. The organic constituents form the great bulk of the tissues of plants; they are completely consumed when the plant is burnt; they are produced by living organs alone, and cannot be manufactured in the laboratory of the chemist. The inorganic constituents, on the other hand, form a small portion of the tissues; they are incombustible, and remain in the form of ash after the organic constituents have been consumed by fire; and they can be produced in the laboratory of the chemist. The former may be called the combustible materials produced by living plants; the latter incombustible materials, found not only in plants, but also in the mineral kingdom. Both are derived originally from unorganized matter, and both enter into the composition of organized structures in a greater or less degree. The vegetable organic constituents are composed chiefly of Carbon (C), Oxygen (O), Hydrogen (H), and Nitrogen (N). The inorganic constituents are composed of metallic bases in combination with oxygen, acids, and metalloids. In the fresh plant there is always a large quantity of water (HO). This is removed by drying. The quantity varies in different plants-succulent and fleshy species containing a larger proportion of water than those which are dry and hard.

After the plants have been dried so as to remove the water, an estimate can be made, by burning, of the relative proportion of organic and inorganic matter—the former being dissipated by the action of fire, and the latter remaining in the form of ashes. Boussingault gives the following

tabular view of the quantity of Carbon, Hydrogen, Oxygen, Botany. Nitrogen, or the organic constituents, and of Ash or the inorganic constituents:—

	WHEAT.		OATS.		r Peas.	Seed.		bs.	.es.
	Grain.	Straw.	Grain.	Straw.	Yellow	Clover	Hay.	Turnips.	Potatoes.
Carbon	46·1 5·8 43·4 2·3 2·4	48·4 5·3 38·95 ·35 7·0		50·1 5·4 39·0 ·4 5·1	46·5 6·1 40·1 4·2 3·1	49·4 5·8 35·0 7·0 2·8	45·8 5·0 38·7 1·5 9·0	5.6	44·0 5·8 44·7 1·5 4·0
	100	100	100	100	100	100	100	100	100

This table shows that the quantity of ash is small, and that of the organic elements Carbon and Oxygen are the most abundant. The relative proportions of the different organic elements, it will be seen, vary in different plants, and in different parts of the same plant. Thus nitrogen is more abundant in the grain than in the straw of where and oats. It is also more abundant in yellow peas and in clover seed, than in the cereal grains and hay. Some of the organic vegetable compounds consist of Carbon. The called Nitrogen, and Nitrogen or Azote, and are bence called Nitrogenous or Azotized. Others are composed of Carbon, Oxygen, and Hydrogen, without the addition of Nitrogen, and are hence called Non-Nitrogenous or Unazotized. In considering these constituents, we shall make some remarks on the elements of which they are respectively formed.

a. Non-Nitrogenous or Unazotized Constituents and their Elements.

The organic compounds, denominated unazotized, are important constituents of all plants. Some of them, such as cellulose, lignine, starch, gum, sugar, and oily matters, are universally diffused over the vegetable kingdom. Others, such as vegetable acids, bitter principles, and resins, are more limited in their distribution. All of these substances, except cellulose and starch, which are organized, and gum, which is amorphous, are crystalline when they can be got in a solid state. Those unazotized matters, which are still subject to the law of crystallization, do not take part in the formation of tissues. Starch and cellulose, on the other hand, are concerned in the development of the organized parts of plants, but in order to effect this, they require the addition of certain azotized products as well as some inorganic matters. Cells and vessels cannot be formed without the presence of albuminous matter, which contains nitrogen and sulphur in its composition, and which cannot be produced without the presence of phosphates. The physicovital energies of the plant effect the union of carbon, oxygen, and hydrogen, in different proportions. These elements, existing in certain states of combination in the atmosphere, are within the reach of plants at all times.

Carbon—enters largely into the composition of plants. It is said to form two-thirds of the weight of dried plants in general. This substance is familiar to us in the form of wood-charcoal, and in its purest state it is seen in the diamond. Charcoal is porous, and has the power of absorbing soluble gases in large quantity, of separating saline and other matters from solutions, and of taking away disagreeable odours. When combined with two equivalents of oxygen, carbon forms carbonic acid (CO₂), and it is in this condition that it is taken up by the leaves and other parts of plants Some maintain that this carbonic acid is derived by plants entirely from the atmosphere, which contains about 1-1000th of its volume of the gas. The quantity contained in the air, although it appears small when compared with the whole

Botany. bulk of the atmosphere, is nevertheless sufficient to supply all the carbon of plants. A room 40 feet long, 24 feet wide, and 16 feet high, will contain in its atmosphere 15 cubic feet of carbonic acid, equal to 28 ounces by weight of carbon. The leaves of plants have a great power of absorbing carbonic acid. Boussingault proved this by passing air containing the usual proportion of carbonic acid over a vine leaf. Even by coming for a few seconds into contact with the leaf, the air was deprived entirely of its carbonic acid. The carbonic acid in the atmosphere is derived from various sources. Amongst the most evident of these are—1. The respiration and transpiration of man and animals. 2. The decomposition of dead animal and vegetable matter. 3. Various processes of combustion on the surface of the earth. 4. Volcanic action going on in the interior of the earth in different

The function of respiration in animals consists in the giving out of carbonic acid, or, in other words, the oxidation of carbon, while the great function of vegetables is the elimination of oxygen or the deoxidation of carbonic acid. The two processes are antagonistic, and a balance is kept up between the carbonic acid given off by animals, &c., and the oxygen given out by plants. A grown person is said to give off 3½ lb. of carbon in a day, and every pound of carbon burnt or oxidized yields more than $3\frac{1}{2}$ lb. of carbonic acid. While active volcanoes give out carbonic acid, there are also extinct ones which do so. The soil in the country on the Rhine, to the south of Bonn, gives out carbonic acid; and all the waters in that district are charged with it. carbonic acid of coal arises from the decay of vegetable

When plants decay they furnish to the soil a large supply of carbon in the form of humus or common vegetable mould. This cannot be taken up directly as food by plants, but it is acted on by air and moisture, and undergoes certain changes by which a portion of carbonic acid is probably formed. It also has the power of absorbing gases, such as ammonia, and sulphuretted hydrogen, as well as saline substances, and of making them available for the use of plants.

Oxygen—is another organic element of plants. It is known to us in a gaseous state as forming 21 per cent. of the bulk of the atmosphere, and as supplying materials for respira-tion and combustion. When one atom of oxygen is combined with one of hydrogen, water is formed, and carbonic acid is the result of the union of one atom of oxygen with two of carbon. In its combinations with metals and metalloids, oxygen forms a large proportion of the solid materials of the globe. All the oxygen in plants seems to be derived from carbonic acid and water. No vegetable contains more oxygen than can be accounted for by these two sources.

Hydrogen—is another element of plants which is known to us in the state of a gas. It does not, however, occur free and in a simple state in nature. It exists in small quantity in animal and vegetable substances, forms 1-9th of the weight of pure water, and enters into the composition of coal. The hydrogen of plants is derived from water.

As carbonic acid and water therefore exist at all times, more or less, in the atmosphere, it appears that the air is the source whence plants procure the carbon, oxygen, and hydrogen, which enter so largely into their composition. At the same time, it cannot be denied, that these elements also exist in the soil, and may be taken up by the roots of plants in the form of carbonic acid and water. The various nonazotized vegetable products (i.e. the products consisting of carbon, oxygen, and hydrogen) can be derived from carbonic acid (CO2), and water (HO), by a process of deoxidation; and as this process is constantly going on in every plant, by means of which oxygen is given out, we may conjecture that it is in this way that the products are formed.1

b. Nitrogenous or Azotized Constituents, and their Elements

Botany.

Another class of substances found in the tissues of plants, and essential to the process of vegetation, consists of carbon, hydrogen, oxygen, and nitrogen (N), with the addition of sulphur (S), and alkaline or earthy phosphates. They are commonly called Nitrogenous or Azotized or Azoto-sulphurized substances. Some authors include them under the general name of Mucus or Protoplasm. The constituents of these organic matters are known by the names of vegetable albumen, fibrine, and caseine. The general name of gluten is given to the glutinous part of wheat which remains after the starch and soluble constituents of the grain have been removed. This gluten consists usually of fibrine and albumen. Wheat contains from 8 to 24 per cent. of gluten; barley 3 to 6; oats 2 to 5.

Nitrogen enters largely into the composition of the tissues of animals, and hence it must be supplied to them in their food. Without the presence of azotized compounds, no blood nor muscle can be formed. Hence the quantity of these compounds in plants, along with phosphates which form bone, indicates their blood-forming or sanguigenous value. Nitrogen is known to us as a gas forming 79 volumes per cent. of the atmosphere, and moderating the effect of oxygen on all oxidable bodies. Like hydrogen, it is sparingly soluble in water. It enters into combination with hydrogen, and forms ammonia, composed of 1 equivalent of nitrogen and 3 of hydrogen (NH₃). Ammonia is given off during the decay of animal tissues, in the form of a pungent vapour, which is readily absorbed by water, and also in combination with other substances, such as carbonic acid and sulphuretted hydrogen. The nitrogen of the air may also, as some think, combine with hydrogen in the soil, and form ammonia. The presence of ammonia in the atmosphere was determined by Saussure in 1806. Ville has recently stated that the nitrogen of the air is assimilated by plants, but his observations have not been confirmed.

In order that azotized matter may be formed, plants must have a supply, not only of nitrogen, but also of sulphur and phosphates. The two latter are derived from the soil, in the form of soluble compounds of sulphuric and phosphoric acids, while the former is derived, according to Liebig, not from the nitrogen of the air, but from the ammonia diffused through it. This ammonia constitutes only 1-10,000th of the bulk of the air at the utmost; it is usually much less. This, however, has been shown to be sufficient for the supply of nitrogen to plants. Ammonia is returned to the air during the processes of putrefaction which go on in dead animals and plants, as well as in the excreta of the former, such as the urine. It is also yielded by transpiration. Thus ammonia is continually sent into the atmosphere, and by the constant movement of the air the supply is diffused. Ammonia is also absorbed by the soil, and may thus be rendered available for the use of plants. It is known also that in some instances volcanic action gives rise to the formation of ammonia. Daubeny believes that the ammonia, as well as the carbonic acid which formed the food of the first plants, was produced, not by processes of animal decay, but by such as were proceeding within the globe prior to the creation of living beings, and that the disengagement of both these compounds has been going on slowly and continually from the earliest period to the present time. Others think that part of the nitrogen of plants is derived from nitric acid and nitrates, and this view is gaining ground. Nitric acid is produced during thunder storms, and in the rain which falls during these storms this acid has been detected in small quantities. The nitric acid in these instances probably proceeds not only from a combination between the

Botany. nitrogen and oxygen of the air, but also from a combination between the ammonia and oxygen. The minute quantity of nitric acid and nitrates in some springs may also supply nitrogen. The nitric acid in these instances appears to proceed from the decay of animal matter, and from the oxidation of ammonia.

All the azotized matters to which we have alluded are formed by a process of deoxidation from carbonic acid (CO2), water (HO), hydrated ammonia (NH3HO), nitric acid (NO₅), and sulphuric acid (SO₃). They all contain much less oxygen than is necessary to convert their hydrogen into water, their carbon into carbonic acid, and their sulphur into sulphuric acid. They are never found alone in plants, but generally two of them together. They cannot exist without the presence of phosphates. Hence the ashes of plants are in part derived from the sanguigenous (blood-producing) matters, such as albumen and fibrine, which enter along with cellulose into the composition of the cell-walls.

2. Inorganic Constituents of Plants.

The terrestrial or telluric food of plants, as it is termed, consists chiefly of certain inorganic matters, the amount of which is ascertained by the ash left after burning. While the organic constituents of plants are destroyed by a high temperature, and undergo decay under the agency of moisture and warmth, the inorganic constituents are incombustible, and do not undergo the putrefactive process. There are at least 12 inorganie elements which enter into the composition of plants:-

> Sulphur, S, as Sulphuric acid, SO Phosphorus, P, as Phosphoric acid, PO₅. Silicium, Si, as Silicic acid, SiO₃. Calcium, Ca, as Lime, CaO. Magnesium, Mg, as Magnesia, MgO. Potassium, K, as Potassa, KO. Sodium, Na, as Soda, NaO. Chlorine, Cl, in combination with metals. Iodine, I, do. do. Fluorine, F, do. do. Iron, Fe, in combination with oxygen, Fe₂O₃. Manganese, Mn, do. do.

Alumina (Al₂O₃), the sesquioxide of Aluminum, which has been noticed by some authors as another inorganic constituent of plants, seems to be an accidental ingredient, being sometimes present, and at other times absent. Mr Stevenson Macadam has recently obtained indications of the presence of Bromine (Br.) in plants.

The quantity of inorganic matter in plants is small when compared with the organic constituents. It is nevertheless essential to the life and vigour of plants. The cellwalls cannot be formed without inorganic matters, and some of them enter into the composition of the azotized substances formed by plants. Thus sulphur and salts of phosphoric acid are necessary for the formation of albumen,. fibrine, and caseine. In some rare instances of plants forming mould, no ash has been detected.

The quantity of ash left by 100 parts of the following plants is thus given by Johnston:-

	Grain.	Straw.
Wheat	1.2 to 2.0	3.5 to 18.5
Barley	2.3 to 3.8	5.2 to 8.5
Oats	1.6 to 2.8	
Rye	1.0 to 2.4	2.4 to 5.6
Indian Corn	1.3	2.3 to 6.5
Field Peas	2.5 to 3.0	4.3 to 6.2
T3	Wood.	Leaves.
Larch 0		6.0
Scotch Fir 0	1.14 to 0.19	2.0 to 3.0
Beech ()·14 to 0·60	4.2 to 6.7

	Wood.	Leaves.
Poplar	. 1.97	$9 \cdot 2$
Willow	. 0.45	8.2
Birch	. 0.34	5.0
Elm	. 1.88	11.8
Ash	. 0.4 to 0.6	
Oak	. 0.21	4.5

Botany.

Thus the quantity of inorganic matter in the same weight of different crops varies. It will be seen, for instance, that the grain of barley yields more ash than wheat or rye. The quantity of inorganic matter also in different parts of the same plant varies, as seen in the grain and straw of cereal grains, and the wood and leaves of trees.

The following comparative results are given by Johnston of experiments made by different chemists regarding the more important inorganic constituent in 100 parts of some of the cultivated plants and trees:-

NAMES OF PLANTS.	Potash and Soda.	Lime.	Magnesia.	Phosphoric Acid,	Sulphuric Acid,	Silica.

From this table it will be seen that the quantities of different mineral matters vary in different plants, and in different parts of the same plant. Silica is present in large quantity in the stems of grasses, while it forms usually a small proportion of grains, leguminous plants, and succulent roots. Phosphoric acid is more abundant in the grain of cereal plants than in the straw; it exists also in considerable quantity in nutritive seeds and in potatoes and turnips. Lime abounds in the stems of beans and peas, in clover, and in the bark and wood of trees; while it exists in small quantity in the cereal plants and grasses. The proportion of lime in the bark of trees is greater than in their wood. Potash and soda enter more largely into the composition of green crops than into that of white crops; they are also more abundant in the wood than in the bark of trees.

Most plants contain more or less of potash and soda in their composition. The former prevails in inland plants,

Botany. the latter in maritime and marine plants. Some succulent sea-shore plants, such as Salsola Kali, and Salicornia herbacea, yield a large quantity of soda in their ashes. Some species of plants which grow both in maritime and inland situations contain a preponderance of soda in the former locality, and of potash in the latter. This is the case with the common Sea-pink (Armeria maritima), Scurvy-grass (Cochlearia officinalis), and sea-side Plantain (Plantago maritima).

The presence of lime has been detected in almost all plants. It is an abundant ingredient of the soil, and is often associated with magnesia. In combination with phosphoric acid, it is an essential ingredient of the nitrogenous matter of cereal grains, and of many other cultivated plants. As sulphate it occurs largely in some of the Charas and Medicks. It sometimes appears as an incrustation on the cells of plants, in the form of carbonate. This is seen in species of the genus Chara (especially Chara hispida) which grow in ponds. In the interior of cells, salts of lime are often seen in a crystalline form, constituting Raphides. Oxalate of lime crystals occur in Rhubarb root; in the best Turkey Rhubarb they constitute 35 per cent. of the dried tissue, in East India Rhubarb 25 per cent., and in English Rhubarb 10 per cent. In some of the Cactus tribe, especially in old specimens of Polocereus senilis, these crystals are so numerous as to render the stem brittle. Crystals of phosphate, sulphate, carbonate, tartrate, malate, and citrate of lime also occur in the cells of plants.

The presence of silica (SiO₃) in plants give solidity and firmness to their stems. The quantity in some plants, such as Equisetum, is very large. In these plants, as well as in grasses, the silica exists in the form of small plates, grains, or needles, as may be shown by the action of sulphuric acid. In the Bamboo (Bambusa arundinacea, and other species) the quantity of silica at the joints is frequently very large, and may be collected in masses, to which the name of Tabasheer is given. In the Diatomaceæ, belonging to the lowest tribe of Algæ, the cells have a siliceous covering, which enables them to retain their form, even after being

acted on by strong acids.

Iodine was considered formerly as an ingredient of maritime and marine plants only, but it has been recently detected in fresh-water plants, as well as in many ordinary land plants, by Chatin and by Macadam. The presence of fluorine in plants was first detected by Will of Giessen, and his observations have been confirmed and greatly extended by Dr George Wilson. It occurs in small quantity in plants, and it is often associated with silica, from which it is separated with great difficulty. Plants growing on the sea-shore, such as Sea-pink and Scurvy-grass, have been proved by Voelcker to contain fluorine. The test for the presence of fluorine is the etching which hydrofluoric acid produces on glass.

Plants derive all their inorganic materials from the soil, and it is consequently of importance to determine the composition of the latter. Some plants, however, are enabled to grow without coming into contact with the soil. Thus in the Botanic Garden of Edinburgh, Urostigma elasticum, Ardisia crenulata, Agave (Littæa) gemmipara, Billbergia nudicaulis, and Phœnix farinifera, have continued to grow for nearly four years suspended in the air, and merely moistened by common water allowed to come into contact with the roots by the capillary action of a worsted thread. Urostigma australe has grown suspended in the air for nearly twenty-five years. The plants have produced leaves and some of them flowers. They derive their organic nourishment from the air, and the quantity of inorganic matter in the water appears to be sufficient to supply their wants in

that respect for a long period. Air-plants or Epiphytes,

such as Tillandsias and Orchids, are usually attached to

rive inorganic matter. In hothouses these Epiphytes have Botany. also a quantity of moss round their roots, which is another source of inorganic matter. Lichens seem to have the power, in many cases, of acting upon hard rocks, and deriving from them inorganic matters. Mulder states that mould plants found on the surface of saccharine and gummy solutions, as well as in vinegar and other organic substances, consist of cellulose and nitrogenous compounds, without any inorganic matter. These plants, according to him, leave no ash on being burnt.

3. Composition and Properties of Soils as supplying Food for Plants.

Having considered the various organic and inorganic matters which enter into the composition of plants and of vegetable products, and having noticed the chief sources' whence plants derive their carbon, oxygen, hydrogen, and nitrogen, we shall now examine generally the nature of the soil, as the source whence the mineral or inorganic matters required for vegetable growth and nutrition are derived. We have seen that the atmosphere, with its carbonic acid, water, nitric acid, and ammonia, is capable of supplying the organic constituents of vegetables. At the same time we have found that sulphur and phosphates enter into the composition of some of the most important sanguigenous (bloodproducing) products. To the salts of sulphuric and phosphoric acid in the soil, we must look, therefore, for the means of enabling plants to assimilate their organic products. While we allow that the atmosphere is the great reservoir whence the organic elements are derived, still we cannot consider it as the exclusive source. It is probable that some of the carbon, oxygen, hydrogen, and nitrogen of plants may be supplied by the soil, and at all events we have seen that these elements cannot be combined in the form of albumen, fibrine, and caseine, without certain mineral matters of telluric origin.

The atmospheric supply of food is pretty uniform, and is not under the control of man. It is to the terrestrial (telluric) supply he must look as that which can be increased and modified by his efforts. The horticulturist and farmer direct their attention to the soil, and by alterations in its composition endeavour to effect changes in the plants which they cultivate. It is therefore of importance to ascertain the mechanical nature and chemical composition of the soil.

The following are the substances which enter generally into the composition of soils: - Silica, clay, lime, and humus or vegetable mould. According to the preponderance of one or other of these ingredients, soils are usually classified.

The presence of sand and gravel in soils renders them loose and friable. Such soils part with moisture easily, and When the proportion of sand is very are usually dry. large, the soils are barren and unproductive. The addition of clay, chalk, and marl, is useful in rendering sandy soils more tenacious. As silica enters more or less into the composition of plants, it must be taken up from the soil by the roots of plants. In order that this absorption may take place, the silica must be dissolved in water. In its uncombined condition it is insoluble, but by combining with alkalies such as potash, it forms soluble silicates, which enter the cells of plants.

Clayey soils contain a large quantity of insoluble silicates, and of alumina, which does not appear to be an essential constituent of plants, although it is occasionally found as an accidental addition to their tissues. The presence of clay has a tendency to make soils stiff and firm, so that they can retain the roots of plants and give them support. Clay soils are usually moist, impervious, and cold. Heavy clay land is improved by draining, by burning, and by mixing chalk and sand with it. Way finds that clay in the soil removes various important matters from the manures put upon

Botany. it, and does not allow the active ingredients to pass off into the drains. It retains the alkalies, as ammonia, potash, soda,

and magnesia.

Calcareous soils contain upwards of 20 per cent. of lime. This substance exists abundantly in the vegetable juices, and hence its presence is required in all productive soils. Calcareous soils exhibit different physical characters according to the proportion of lime, clay, silica, &c., which enter into their composition. The addition of lime to soils is often highly beneficial, by destroying noxious weeds, and by preventing disease in crops. Lime, in combination with phosphoric acid, is a valuable ingredient of soils. Sulphate of lime or gypsum seems to be useful, not merely in supplying sulphuric acid and lime, but also in fixing ammonia. In marly soils lime exists in proportions varying from 5 to 20 per cent. In loamy soils lime is in smaller quantity, and the clay does not exceed 50 per cent.

Humus soils contain much vegetable mould. This is in itself insoluble, and cannot be taken up by plants. By the action of air and moisture, &c., the humus is decomposed, and various acids are formed, which seem to be capable of supplying carbon to plants. Vegetable moulds also absorb gases, such as ammonia, in large quantity, and thus supply

nutritive matter to plants.

The alkalies, potash and soda, are important constituents of plants, and they exist in greater or less quantity in soils. They enter into the composition of minerals, such as felspar. They are taken up by plants in combination with acids. They render silica soluble, and they are essential to the development of acids, such as oxalic, citric, and malic, with which they are found in combination. They appear to replace each other in certain circumstances. In many fertile soils magnesia exists in combination with carbonic acid, phosphoric acid, and lime. In flax there is a large proportion of magnesia. In its caustic state magnesia is injurious to vegetation.

Iron has been detected in greater or less quantity in the ashes of all plants. It exists in the soil in combination with oxygen, sulphur, and carbon. The oxides of iron are found, more or less, in all soils, and the peroxide, which is the most abundant, imparts that reddish colour so often observed on the earth's surface. The protoxide of iron is of less value than the peroxide for vegetation, as it readily forms salts which are injurious to plants. It frequently abstracts oxygen from the soil, and becomes fully oxidized. Manganese exists sparingly in plants, and it is found in the soil combined with peroxide of iron. The presence of nodine in plants has been fully recognised by many observers. Chatin believes that there is an appreciable quantity of iodine in the atmosphere, in rain water, and in the soil, varying in different districts, and that the relative amount of iodine, in any one locality, determines, to a great extent, the presence or absence of certain diseases, such as goitre and cretinism. Mr Stevenson Macadam, from a very accurate series of experiments, has been led to the conclusion, that air and rain water do not contain iodine, at least in such quantity as to be detected by the most delicate tests. It is probable that it is derived from soluble iodides in the soil. Iodine is said to exist in coal and in the waters of the globe. The waters from igneous rocks, and from the rocks of the coal formation, are said to contain a considerable quantity of iodine. It is found in combination with sulphur, the ores of iron and manganese, and the sulphuret of mercury.

The sources of the Fluorine found in plants, Wilson regards as pre-eminently two-Simple fluorides such as that of calcium, which are soluble in water, and through this medium are carried into the tissues of plants; and Compounds of fluorides with other salts, of which the most important is probably the combination of phosphate of lime with fluoride of calcium. This occurs in the mineral king- thus rendered available for plants.

dom in apatite and phosphorite, and in the animal kingdom Botany. in bones, shells, and corals, as well as in blood, milk, and other fluids. Fluorides are much more widely distributed than is generally imagined. They exist in well, river, and

The productiveness of soils is very various. Some are entirely barren, such as quartz rock. This kind of soil is seen in many mountainous districts in which the bare quartz rock continues to show itself without any vegetable covering whatever. Others contain materials fitted for nourishment, but not available until they are disintegrated. This is the case with many granitic rocks containing valuable nutritive matter which can only be taken up by plants after the rocks have been pulverized by the action of the weather. Some hard granites which are not thus acted upon are barren. Some soils are unproductive on account of their physical characters, such as very stiff clays; others are so on account of being too loose and sandy; while others, from excess of water, are too moist, and require draining before they can be productive. The presence of substances in an unavailable form is the most common cause of sterility in soils. Barren felspar soils may be rendered fertile-by exposure to the air, or in other words, by lying fallow; by frequent ploughing and turning up; by the use of quicklime, which acts by accelerating the decomposition of felspar and clay, and separating the silica and potash from the former; by burning or calcination which acts in the same way as lime. Thus fallow, ploughing, liming, and burning act in the same way on barren felspar soils, by causing decomposition, and separating the materials required for the nourishment of plants. They all promote the solubility of different parts of the soil. Below the ordinary soil there occurs what is called the subsoil, in which there is less organic matter than on the surface. Into this soil many soluble matters are carried down by rains. The effect of subsoil and trenchploughing is to bring up these matters and render them available for the use of plants. The beneficial results of this kind of ploughing will depend upon the composition of

4. Rotation of Crops and Application of Manures.

Some plants require certain inorganic matters in larger quantity than others, and it is upon the knowledge of this that the rotation of crops is founded. The soil is constantly losing inorganic matters. By continuing to cultivate the same crop, we deprive the soil, to the depth to which the roots extend, of certain materials, while others are left nearly untouched; but by alternation of crops the latter may be made available for the purposes of growth. Farmers on this account have different crops succeeding each other in the same field. Wheat, barley, and oats are described as silica plants; peas, beans, and clover as lime plants; turnips and potatoes as potash plants. These crops, from the difference in their predominant inorganic ingredients, are made to alternate with each other. In some virgin soils, rich in phosphates and other inorganic matters, the same plants may be cultivated successfully for many years.

There is often a great quantity of fertilizing matter in the soil, but not in a condition immediately available for the growth of plants. Hence, in some cases where the crop is deficient, there are valuable materials still in the soil unassimilated. Thus phosphates exist often potentially in a dormant state in the soil in great abundance, but it is not until they have been brought into a soluble form that they are of any use as the food of plants. It is of importance for an agriculturist to discover the dormant inorganic materials, and to adopt means of rendering them available. Allowing the ground to lie fallow, and stirring and pulverizing of it, are methods by which air and moisture are admitted, and time is allowed for the decomposition of the materials, which are Botany.

The materials of which plants are composed, and which are all withdrawn from the unorganized world, are given back to the air and soil again by the disintegration of the living structures of which they have formed a part. If plants were not used for food, they would by their decay restore all that they had taken away for the purposes of growth. But as they contribute to the nourishment of man and animals, it follows that a portion of vegetable matter is constantly removed in order to build up the animal structures. This portion must be again supplied in order that the plant may be nourished. This is the principle of the application of manures. The farmer and horticulturist add to the soil what has been removed from it by crops. In order to do this properly, there must be a knowledge of the composition of the plant, of the soil, and of the manure; and hence the importance of accurate chemical analyses. In addition to this, attention must be directed to the functions of plants, and to the mode in which they take up nourishment; and the materials of growth must be supplied in such a way as to be made available for the purposes of plant-life.

The object of manuring is to improve the properties of the soil, and to supply what has been taken from it by crops which have been used for the food of man and animals. We may either supply the whole or some portion of the vegetable constituents in a soluble state, or we may add to the soil something which will decompose and act on its insoluble ingredients, so as to render them fit for the use of plants. Natural manures, such as those of the farm-yard, are excellent, because they restore to the land nearly all the substances which have been taken from it. Other manures supply one or two ingredients only. The exposure of the soil to the influence of the weather tends to make up for loss, by causing the decomposition of substances previously unfit for vegetable nutrition. Fallow then acts, in a certain degree, in restoring the fertility of the soil, but it will not give us all that is required, and, moreover, involves loss of time and money.

In the case of cultivated plants, those manures are considered the most valuable which furnish the materials necessary for forming the azotized compounds required for the sanguigenous food of man and animals. Hence the importance of manures containing ammonia and phosphates, substances which do not usually exist abundantly in the soil, and which are annually required in large quantity by crops. It has been found by comparative experiments that the quantity of gluten in wheat and other cereal grains is increased by the use of ammoniacal and phosphatic manures. The sewerage of towns, in this point of view, is one of the most valuable manures, and it is to be regretted that so little is done to save it for the purposes of the farmer and horticulturist.

The soil has a great power of absorbing ammonia, and supplies it gradually to the roots of plants in a state fit for their nutrition. The vigour of plants is much increased by the judicious application of ammonia either in the soil or in the air. It is essential that ammonia should be supplied in moderate quantity at a time, and at the proper season. It requires also the presence of phosphates, in order that its full effect may be secured in the production of nitrogenous matter. Some manures give off ammonia in large quantity by a process of fermentation; and in order to prevent the loss thus occasioned, it is frequently necessary to add sulphuric acid or sulphate of lime, so as to procure a non-volatile sulphate of the alkali.

Manures may be divided into—1. Farm-yard manure, containing all the ingredients required for a crop. This, when applied to the soil, is slowly decomposed, and its effects extend over several years, so that it exerts a beneficial influence upon all the crops of a rotation. It may be called in general a slowly-acting manure. 2. Special manures, composed of ingredients which are intended for the special bene-

fit of the crop to which they are applied, while comparatively little effect is expected to be produced on those that succeed it. These may be called rapidly-acting manures. The first is of importance for cereals which are slow-growing plants; the second are valuable for green crops, which of all others require the greatest quantity of nourishment in a given time. While ammonia may be supplied by both, still, in the former it is slowly produced by a gradual combination between nitrogen and hydrogen, while in the latter it is ready formed, and capable of being at once used by the plant.

Farm-yard manure consists of complex animal and vegetable compounds, which by free exposure to the air undergo a kind of fermentation, so as to be converted into other substances, of which carbonic acid and ammonia are the most important. This fermentation is promoted by moistening and turning over the manure, in order to permit the free access of air. It may be applied in a solid or in a more or less fluid state. The term liquid manuring is properly given to the use made of the urine of cattle, containing a large amount of urea, which, by decomposition, becomes carbonate of ammonia. Of late, however, this has been mixed with other matters from the farm-yard, as well as with carbonaceous and peaty substances, and the whole has been pumped over the field in the form of a fluid containing solid ingredients suspended in it. This kind of fluid manure is more beneficial than liquid manure properly so called.

Among Special manures there are some which supply ammonia and phosphates either separately or united, others furnish acids or bases, such as Sulphuric acid, Nitric acid, Potash, Soda, Lime, &c. The liquor of gas-works and soot owe their manurial value principally to ammonia. Bones are prized on account of the phosphate of lime in their composition, which amounts in general to about 50 per cent. In place of using bone-dust, which acts slowly, from the insoluble nature of the phosphate of lime, farmers are in the habit of mixing bones with sulphuric acid, and thus getting a soluble compound of phosphoric acid and lime (superphosphate), which, when dissolved in water, is easily taken up by the roots of plants. The addition of sulphuric acid also acts beneficially in supplying sulphur for the azotized compounds. One of the most important special manures is Guano, or the dung of sea-fowl, which has accumulated for centuries in some parts of the coast of South America and Africa, and now forms enormous deposits. Its value depends partly on ammoniacal salts and partly on phosphates. Some guanos, as Peruvian, Anagamos, and Bolivian, are rich in ammonia; while others, as Patagonian and Saldanha Bay, are rich in phosphates.

Various other special manures have been recommended, containing one or two of the inorganic constituents of plants. Nitrates and Carbonates of Potash and Soda appear to act by furnishing alkaline matter as well as nitrogen and carbon. Sea salt (Chloride of sodium) is considered by Mr Way as beneficial both to white and green crops. thinks that it probably acts on the silicates of lime present in the soil setting the lime free, and acting on the silica so as to render it fit for the purposes of vegetable life. In the case of cultivated plants which naturally grow near the sea, such as Sea-kale, Asparagus, Cabbage and its varieties, salt may be expected to be useful. Lime acts beneficially as a manure in the case of some plants, prejudicially as regards Occasionally a green crop is grown with the view of being afterwards ploughed into the soil, and of supplying, during its decomposition, materials which had been taken up by its roots from a considerable depth in the soil. This is called green manuring. Sea-weeds are also used as

II. PHYSIOLOGY OF THE DESCENDING AXIS OR ROOT.

The Root is the descending system of the plant, and is

Botany. the organ directly concerned in the absorption of nourishment from the soil. In its earliest state it is a cellular prolongation from an axis which is common to it and the stem. In cellular plants, the root consists also of cells. Root-cells are developed in a downward direction, and the fibrils spread through the soil, so as to absorb nutriment and to fix the plant firmly. The additions to roots are made at their extremities, and there it is that the chief absorbing cells are situated, constituting what have been called Spongioles (Fig. 62). Connected with young roots there are hairs or cellular prolongations from the epidermis, which also absorb fluid food. These hairs die early with the epidermis from which they sprung; the root then becomes covered with a corky layer, while its extremity continues to grow and send out fresh hairs. Any injury done to the absorbing extremity interferes more or less with the proper nutrition of the plant.

As plants are fixed to a spot, their food must be always within reach, and it is requisite that the roots should have the power of spreading, so as to secure renewed supplies of nutriment. A beautiful provision is made for this by the elongation of the roots taking place at their extremities, so that their advancing points are enabled easily to accommodate themselves to the nature of the soil in which the plant grows. If roots had increased by additions throughout their whole extent in the same way as stems, they would in many instances, when meeting with an impenetrable soil, have been twisted in such a way as to unfit them for the free transmission of fluid. But by the mode of lengthening at the point, they insinuate themselves easily into the yielding part of the soil, and when obstacles are presented to their progress, they wind round about them until they reach a. less resisting medium. They are thus also enabled to move from one part of the soil to another, according as the nourishment is exhausted.

The root, in its growth, keeps pace with the development of the stem and its branches. As the stem shoots upwards and develops its leaves, from which water is constantly transpired, the roots continue to spread, and to renew the delicate cells and fibrils which absorb the fluid required to compensate for that lost by evaporation, or consumed in growth. There is a constant relation between the horizontal extension of the branches and the lateral spreading of the roots. If the roots are not allowed to extend freely, they exhaust the soil around them, and are prevented from receiving a sufficient supply of food. The plants in such a case, deprived of their proper means of support, become stunted and deformed in their appearance.

If we wish trees to be firmly rooted, we must allow the branches to spread freely. When they are so planted that the branches and leaves of contiguous trees do not interfere with each other, and thus all parts are exposed to air and light equally, the roots spread vigorously and extensively, so as to fix the plants in the soil, and to draw up copious supplies of nourishment. But in crowded plantations, where the branches are not allowed freedom of growth and exposure, and the leaf-buds are consequently either arrested or feebly developed, the roots, also, are of necessity injured. They do not spread, and the trees are liable to be blown over by the wind; they exhaust the soil in their vicinity, circumscribed by the roots of the trees around; their functions become languid, and thus they react on the stem and branches, so that the additions to the wood are small, and the timber is of inferior quality. The spreading of roots in favourable circumstances is often remarkable. Thus, the roots of trees and other plants, when they reach reservoirs of water, as wells or drains, are found to increase very rapidly, and extend to a great length. Drains are sometimes completely blocked up by roots, in consequence of a single fibril entering at a small crevice, and then expanding into a large fibrous mass.

Roots, by depriving the soil of certain nourishing matters, Botany. render it unfit for the growth of the same species of plant, although it may still be able to contribute to the growth of other species. This is the principle of the rotation of crops, to which allusion has already been made. This exhaustion of the soil affords an explanation of the phenomenon called fairy rings, consisting of circles of dark green grass seen in old pastures. These have been traced to the successive generations of certain fungi spreading from a central point, exhausting the soil at first, and afterwards by their decay, causing a luxuriant crop of grass.

The spongioles and cellular hairs of the fibrils of roots absorb fluid food, and by diffusion communicate the matter absorbed to the neighbouring cells, and these in turn send it through their membrane upwards into the stem. Senebier proved by experiments that the absorption takes place principally by the cells at the points of the roots. After the corky layer is formed, the cells seem to have less power of taking up fluids through their walls. The imbibition by the roots may be traced in part to the process of endosmose already described, and in part to certain vital actions going on in the cells. By virtue of the chemical composition of its cell-walls and juices, and by vital affinity, a plant absorbs one substance more quickly than another, and consequently in a given time more of one than of another.

That the roots of plants have a certain power of selection was proved by the experiments of Saussure. He immersed the roots of plants in water, containing in solution an equal weight of two different salts, and when the plants had ab sorbed half the water, he took them out and evaporated the remaining water, so as to determine how much of the salts remained. This of course indicated what the plants had taken up. The salts were not absorbed in equal quantities. This difference in the proportion of salts taken up was only observable so long as the roots were entire; for when their extremities were cut off the different saline matters were taken up in the same proportion. The absorption of saline matters by the roots of plants varies in individual plants of the same species, as well as in plants belonging to different species. The absorption, according to the observations of Saussure, does not seem to have reference to the value of the substances as nutriment. Substances are taken up which prove injurious to plants. Trinchinetti placed different species of plants in mixtures of two salts-nitre and common saltwhich do not decompose each other, and he found that one plant absorbed the one, and another plant the other salt, in preference.

Besides absorption, it has also been stated that excretion takes place by roots, or in other words, that matters which have been taken up from the soil, and which are not required for the use of the plant, are again returned by the This subject was investigated by Macaire, who looked upon these excretions as injurious to plants. The recent observations of Gyde and others, however, lead to the belief that the excretions of roots are in small quantity, and that they do not possess the deleterious properties which were attributed to them. It is probable that the substances given off by roots may be referred to a process of exosmose.

Some roots which do not ramify have reservoirs of nutriment stored up in the form of nodulose or tubercular masses. This occurs in terrestrial Orchids, and in Dahlias. In the case of Spondias tuberosa, the tubercles of the roots contain a large quantity of watery fluid. In climbing plants, such as Ivy, the root-like processes by which they are attached to trees or walls seem to be means of support rather than organs of nutrition. Aerial roots take up nourishment from the atmosphere chiefly. This is the case with the roots of many Epiphytic Orchids, and in consequence of not being in a resisting medium like the soil, the elongation in them seems not to be confined to the extremities, as

Botany.

Botany. shown by the experiments of Lindley on Vanilla and Aerides cornutum. The roots of these Epiphytes or air-plants may derive some nourishment from the decomposition of the bark of the trees on which they grow, as well as from the decay of mosses, lichens, &c., which accumulate around them, but their principal nutriment appears to be supplied by the water, carbonic acid, and ammonia of the air. Roots, when exposed to the air, lose their fibrils, and take on the functions of stems, so as to produce leaf-buds.

Some plants, in place of sending their roots into the soil, or extending them into the air, have the power of attaching themselves to other plants in such a way as to prey upon their juices. These are called Parasites. Some of them have green leaves, such as the Mistleto; others have only white or brown scales, as the Scalewort and Broom-rape. In the former, the juices, after being taken up by the plant, are altered in the leaves by exposure to air and light. Some of these are root-parasites, in other words, become attached to the roots of other plants; as Broom-rape, Eyebright, Bastard Toad-flax, and Cow-wheat; others are stem parasites, growing by attachment to the stems of other plants; as the Mistleto, Myzodendron, Rafflesia, and Dodder.* All of them send cellular prolongations more or less deeply into the tissue of the plants on which they feed, and by means of these, which act as roots, they derive nutriment. They often cause great injury to the plants on which they

III.-PHYSIOLOGY OF THE ASCENDING AXIS OR STEM.

The stem produces buds which are developed as branches, leaves, or flowers. It conveys fluids in various directions, and allows the organs of plants to be exposed to the influence of air and light. In the case of subterranean stems, the leafy and flowering branches are sent upwards into the air, and they perform the functions of aerial stems. Herbaceous stems carry on their functions for one year, or for a limited period, while those of a woody nature continue to perform their functions for many years. While the former attain a moderate size, and perish after a brief period of existence, the latter are permanent, and frequently, as in the case of trees, acquire a great height and diameter. Herbaceous axes occasionally attain a large size, as may be seen in Bananas. Many cone-bearing trees, as Pines, Spruces, Larches, Araucarias, Sequoia, and Wellingtonia, have stems varying from 100 to 300 or more feet in height. Other dicotyledonous forest trees in Britain sometimes attain the height of 120 feet; while on the Continent and in America, they are sometimes 150 feet high. Monocotyledonous stems, such as those of Palms, are usually unbranched, and their height is sometimes 150 or even 180 feet. The Cable Palm runs among the trees of the forest to the length of 500 feet. Acotyledonous stems, as those of species of Alsophila, Dicksonia, and other Tree-ferns, attain a height of 50 or 60 feet. Some cellular stems also attain a large size. Hooker mentions a sea-weed—Lessonia fuscescens—with a trunk 5-10 feet long, and as thick as the human thigh. Stems often attain a great thickness. The stem of the Dragontree of Orotava is 70 feet in circumference; that of the Baobab has a circumference of 90 feet; some Cedars of Lebanon at the present day have a girth of 40 feet. Chestnut trees have occasionally a circumference of 60 feet, and trees of the South American forests are mentioned by Martius with a girth of 84 feet at the base of the trunk. While some Palms, such as Kunthia montana and Oreodoxa frigida, have slender reed-like stems; others, such as Cocos butyracea and Jubæa spectabilis, have trunks which are three or even five feet in diameter.

By means of terminal and lateral buds, stems increase in height and diameter. In their earliest state they are composed of cellular tissue, in the midst of which there is de-

veloped vascular tissue, which is arranged in different ways, as already described. The cellular tissue of the young dicotyledonous stem is early separated into two portions—a medullary or inner, and a cortical or outer-by the formation of vascular and woody bundles, which increase in concentric zones. In its young state, the pith is succulent and seems to be a reservoir of nourishment for the embryo plant during its early growth. The sheath surrounding the pith contains numerous spiral vessels, which extend upwards and outwards to the leaves. In ordinary circumstances these vessels contain air. The outer cellular portion of the stem constitutes the bark, which protects the other tissues, and often contains secretions, such as gums, resins, and alkaloids. When the bark is green, it seems to exercise the same functions as leaves. It is united to the pith by medullary rays which give a character to the wood. The cells and vessels of the stem are concerned in the circulation of sap, as will be afterwards noticed, and the woody tubes, when fully formed, give stability and durability to the

Between the pith and bark, as well as at the extremities of the buds and roots, there exist cambium cells, which, according to Schacht, form the first stage of the vascular bundles, and give origin to the proper parenchyma or nourishing tissue. A cylindrical layer of this cambium or organizing tissue is distributed in all the most perfect plants, so as to divide the parenchyma into pith and bark, as well upwards in the stem, as downwards in the root. In Dicotyledons, this cylindrical layer, called by Schacht the *thickening* zone, is active as long as life remains. It is by means of it that the stem enlarges—the cells of the tissue forming, toward the interior, new wood, and, towards the exterior, new bark.

In Monocotyledons and the higher Cryptogams, the thickening zone—in other words, the cylindrical layer of organizing tissue—continues active only for a short period of time, and hence these plants do not enlarge beyond a certain point; and at length they grow only in one directionnamely, in height. This thickening layer of cambium, while it adds to the size of the stem of Monocotyledons, causes the increase of the vascular bundles. After a certain period, however, this zone becomes woody, and then the vascular bundles only grow at their extremity, by means of unchanged cambium cells which are in immediate connection with the bundles. This cambium of the vascular bundles is essential to them, and gives them their character. In Monocotyledons it is situated in the centre of the bundles, and is surrounded by spiral, pitted, or woody vessels; in Cryptogams it surrounds the vascular bundles. The vascular bundles in both these classes of plants are limited, and they can only increase laterally by ramifying, as in Dracæna and some Tree-ferns.

The cambium appears to be the immediate agent in the development of new tissues. The origin of the cambium cells, and the mode in which the wood of trees is formed, as well as the influence exerted by the leaves and green parts of plants, have long been subjects of dispute among physiologists. Grew and Malpighi thought that the new woody layers were formed by the bark, while Hales maintained that they were formed from the previously existing wood. Dr Hope loosened the bark of trees, and found new layers of alburnum formed on its inside. Duhamel put plates of silver between the woody and cortical layers, and found the new formation on the outside of the plates; he also removed a portion of the bark of a plum-tree, and replaced it with a similar portion of a peach-tree, and after union had taken place, he ascertained that at the point of junction a thin layer of wood had been formed by the peach bud, and none by the wood of the plum. Hence these experimenters concluded that the new wood was produced by the bark. De Candolle, as the result of his observations, maintained that both the bark and the wood were concerned

*Plate CXXV.

Botany. in the formation of woody matter. All appear to agree in looking upon the cambium layer as concerned in the development of the wood.

We have seen that recent authors have ascertained more fully the nature of cambium, and that they consider it in the light of active formative tissue, developing cells and vessels in an upward and downward direction. Some adopt the view that there are in reality two systems in plants, an ascending and a descending one; and that what takes place in the sprouting of the embryo continues to be manifested during the life of the plant. This view, variously modified, was adopted by De la Hire in 1708, was supported by Darwin and Knight, and was particularly espoused by Aubert du Petit-Thouars in 1806, and subsequently by Gaudichaud and others.

According to Petit-Thouars and Gaudichaud, we see in the embryo a radicular and a caulinary portion, the one having a tendency to ascend, the other a tendency to descend. In both of these systems cells and vessels of different kinds occur. In Dicotyledons the ascending system is connected with the medullary sheath, and passes into the buds and leaves, while the descending system is the woody tissue sent down from the leaves between the sheath and the bark. The woody fibres of the leaves, favoured by the cambium, are developed from above downwards. In the wood the ligneous tissue of the upper leaves envelopes that of the inferior ones, while in the bark the fibrous tissue is inserted in the reverse way—the internal layer, corresponding also to the superior leaves, being the newest. The extension of the cellular tissue of the stem takes place in a horizontal or transverse direction.

The Radicular or vertical theory of wood formation has been supported by reference to the arrangement of the vascular bundles in Palms (Fig. 85) and Dracænas, and to the development of aerial roots from different parts of the stems of Screw Pines (Fig. 66), Figs, Vellosias, and Tree-ferns. Many travellers, such as Gardner, who examined Palms in their native countries, have espoused the vertical theory of wood formation. In these plants the bundles of woody vessels can be traced from the base of the leaves, taking a peculiar curved direction downwards, and interlacing in a remarkable manner. In many Palms the fibres burst externally through the stem, and appear as roots. In the case of Screw Pines, the formation of external or adventitious roots is very remarkable; in them the thickness of the stem is diminished below the points whence the roots proceed, as if the woody matter had appeared externally in place of proceeding internally. Adventitious descending roots are also seen in many of the Fig tribe, such as the Banyan (Fig 65) and the Peepul tree. In Tree-ferns the lower part of the stem is often much enlarged by these aerial roots being applied closely to it. Brown says that in Kingia (an Australian plant) the leaves send down, between the true stem and the bases of the petioles which form the only bark of the tree, a series of adventitious roots closely covering the stem, and resisting to a great degree the action of external destructive agents, such as fire. A further development of this root structure is seen in Barbacenia and Vellosia, where the whole outer part of the stem is made up of interlaced roots, which are traced inwards and upwards to the leaves. In Bananas and Plantains, as grown in the hothouses of Britain, we often see roots proceeding from the base of the leaves forming the herbaceous shoot. Roots are to be seen proceeding from sound portions of the wood of Willows, and running into those which are decayed, and wounds made in the stems of trees are sometimes covered by radicular fibres sent down from the upper

These views of Gaudichaud and others have been opposed by many able physiologists, more especially by Mirbel, Payen, Naudin, and Trecul. Mirbel has examined in a

particular manner the development of the Date, and he has Botany. been led to the conclusion that the fibres increase from below upwards, and not from the leaves downwards. He says that a Monocotyledon produces at its summit a mass of cellular tissue called a phyllophore, into which the vessels from the stem penetrate to form the vascular system; that after this the leaves are produced; that the vessels come from the internal periphery of the young part of the stem, arising at all heights, and that the roots have at first no immediate connection with the leaves. Trecul has examined the stems of Dicotyledons, and has been led to deny the downward tendency of the wood formation. He states that after the bark has been removed, a new layer of woody tissue and bark is formed at detached points, into which the medullary rays are continued directly without the slightest interruption. He thinks that the woody tissue is a lateral development from the already existing longitudinal cells; that fresh bark is formed on the woody tissue by the development of cells from the tissue, while the medullary rays penetrate directly into the new patches of wood; and that the woody fibre is equally capable of throwing off lateral cells, which, while in immediate connection with the old fibre, exhibit more or less imperfectly the character and form of the tissue from which they arise, while the free ends are mere parenchymatous cells. According to him the fibro-vascular bundles are not continued without interruption from the extremities of the leaves to the rootlets; the diameter of the stem may increase without the intervention of ligneous fibres descending from the leaves or buds; and the tissue of the wood and vessels, as well as the medullary rays and bark, are formed in situ, independently of the tissues higher up.

Amidst these opposing views, it is difficult to come to a decided conclusion. There is undoubtedly an ascending and a descending system in plants—a stem developed in an upward, and a root in a downward direction. The leaves are also of importance in the formation of wood, and the cambium cells are the active tissue of the stem. In so far all are agreed. The points of difference are the exact relation which the leaves bear to the woody fibres of the stem, and the direction in which these fibres are developed. The peculiar arrangement of fibres in the stems of Palms, and the production of aerial roots from various stems, favour in some measure the vertical theory of wood formation; while the woody excrescences occurring in the bark of some trees, and the production of particles of woody matter in the centre of decorticated portions of wood, and at the lower part of wounds, as shown by Trecul, seem to show that woody fibres are formed in some instances without any direct connection with leaves. While the weight of authority is in favour of the views recently propounded by Trecul, there are many facts brought forward by Gaudichaud which still require explanation, and which are not easily accounted for, unless we suppose an upward and downward tendency to be impressed on the tissues of the stem and of the buds, in the same way as on the embryo at its earliest growth. Physiologists in general concur in believing, that without the presence of leaves on the stem, no woody matter is formed.

IV .- PHYSIOLOGY OF THE LEAVES.

The leaves are arranged upon the axis in such a way as to be fully exposed to the influence of air and light. They are thus enabled to perform very important functions. As regards the development of leaves, Trecul states that some are developed from below upwards, as in the Lime; others from above downwards, as the pinnate leaves of Sanguisorba officinalis and Rosa arvensis, and the digitate veins of radiating leaves; a third set, as the leaves of Acer, exhibit both kinds of development, the lobes being formed from above downwards, and the secondary venation and toothing

Botany. from below upwards; and a fourth set, as those of Monocotyledons, have their veins formed in a parallel manner, the leaf lengthening by the base of the blade or petiole. Leaves having sheaths, or their lower portion protected by other organs, grow most at the base; those of which the whole petiole is very early exposed to the air, grow more towards the upper part of the petiole. The fluids which reach the cells and vessels of the leaves undergo changes by which they are elaborated and fitted for the formation of various vegetable secretions. In ordinary plants the non-development of the leaves arrests the formation of woody matter and of many important products. Leaves have the power of absorbing carbonic acid, ammonia, water, and aqueous solutions. They also exhale a certain amount of water, and they give off gaseous matters, especially oxygen. Thus leaves, in the performance of their functions, absorb and exhale watery and gaseous substances.

1. Absorption by Leaves.

When liquids are brought into contact with the leaves of plants, absorption takes place. Bonnet found that plants of Mercurialis, with the surface of their leaves in contact with water, absorbed as well, and kept for a time nearly as fresh as those of which the roots were immersed in the liquid; that the under surface of ordinary leaves took up liquids rapidly in consequence of the thinness of the cuticle, the laxity of the cellular tissue, and the presence of stomata; and that the thick and hard epidermis on the upper surface having few stomata, presented an obstacle to absorption. The hairs which occur especially on the under surface of leaves, seem to act like cellular rootlets, and to absorb moisture. Hoffmann ascertained that liquids are absorbed by the leaves in large quantity, and that in such cases they pass downwards by the tracheæ and the prosenchyma immediately surrounding them, displacing for a time the air usually contained in the spiral vessels. He states that after every fall of rain or dew there is an absorption by the leaves, and that this is followed by an immediate descent of sap. The absorption takes place with greater or less rapidity according to the nature of the leaves, and the fluid passes through the inter-cellular spaces, as well as the cells and vessels. The greater and the more rapid the absorption, so much the more have the fluids a tendency to enter the spiral vessels. The absorbing power of the epidermis of leaves varies. When composed of delicate thin-walled cells, with numerous stomata, the imbibition of liquids is carried on rapidly; but when the epidermal cells are hardened, and have thick walls, absorption is much impeded. Some gaseous matters are taken up rapidly by leaves. Boussingault found that air was speedily deprived of carbonic acid by coming into contact with the leaves of the Vine for a few minutes. Chevandier calculates that the trees of a forest, during the five summer months in which they bear leaves, withdraw from the column of air around them about 1-9th of its contents of carbonic acid.

Some researches have been made by Garreau in regard to the absorption of different liquids by the external surfaces of plants, and more especially by the leaves. In making his experiments, he employed endosmometers (long tubes with large open bulbs at the end) of nearly equal calibre, the diameter of the orifice of the ball being in all of them about half an inch, and the diameter of the tube about one-twelfth of an inch. Each epidermis, or cuticular surface, was fixed to the end of the endosmometer by means of a wax thread, and covered by wax at the margin. The fluid in the bulb of the endosmometer was a solution of one part of sugar in two parts of water. He found that the young epidermis is endosmotic, or has the power of absorbing fluids, but that it loses this property as it gets old. He attributes the absence of absorption in the epidermis of old leaves to the fatty or waxy matter which covers them,

and with which they are impregnated. His conclusions are: Botany. -1. The cuticle possesses a decided endosmotic property, the intensity of which is greater the younger the organ which it covers; when leaves become old they seem to lose their absorbing power. 2. The absorption of the cuticle is greater, the less there is of fatty or waxy matter in it. 3. The cuticle which covers the superior surface of the ribs, and more especially that which covers the petiole at the point where it joins the stem, is that part of the foliar surface which has the most marked power of absorption. 4. In some instances in which the cuticle or outer skin is absorbent, the epidermis or inner layer of integument presents obstacles to absorption. 5. Simple washing with distilled water, more especially washing with soap and water, augments the absorbing property of leaves. 6. When leaves have lost their power of absorbing water, they can still take up carbonic acid.

2. Exhalation by Leaves.

a. Exhalation of Watery Fluid, or Transpiration.

The leaves of plants, in the performance of their functions, give off a quantity of watery fluid. This constitutes what is commonly called Transpiration. The quantity of liquid transpired varies according to the structure of the leaves and the nature of the climate. When the texture of the leaf is hard and dry, as in Banksias, Proteas, and many other Australian plants, or the skin covering the leaf is thick and dense, as in the American Aloe and the Oleander, the

amount of transpiration is comparatively small. In this way certain succulent plants, as Cactuses (Fig. 142), are enabled to withstand the effects of dry and hot climates, without being destroyed by the great loss of water by exhalation. The thick covering of hairs on some leaves, as on those of Culcitium, seems to be connected also with the amount of transpiration. Some very hairy plants, as Shepherd's Club, have been known to resist the effects of great drought. The hairs have the power of becoming more

Fig. 142.

hairs have the power of becomes of Melon-Cactus, or less erect, and of absorbing the dew, Species of Melon-Cactus, they lie flat on a succulent plant. the surface and hinder the passage of fluid. In leaves with a very thin epidermal covering or skin the exhalation is great.

Schacht remarks that in the epidermis of plants the external sides of the cells become thickened generally more than the internal. They offer, especially when corky, resistance to the evaporation of the liquids in the parts filled with sap. They would completely prevent transpiration, were it not for the presence of stomata, which allow gaseous and vaporized substances to be exhaled as well as absorbed. The epidermis of the stem, as soon as it dies, is replaced by cork, which, when completely formed, prevents all transpiration, although by its porosity it may condense gases at the surface of the plant. The presence of corky matter in the cell-walls, which has been noticed by Mitscherlich, may thus materially modify the functions of absorption and exhalation. In order that leaves may perform their functions properly, there must be a certain degree of exhalation. If from the leaves being covered with soot or dirt, or with the cottony productions of scale insects, the proper amount of exhalation is prevented, much injury is done to the plant. Hence, the importance of having the leaves of plants, when growing in hothouses and conservatories, well washed and cleaned, in order that they may perform their healthy functions.

The passage of vapour through the pores of the leaf is an imperceptible process, which is constantly going on, and the existence of it is ascertained by its effects. Woodward and

Botany. Hales made various experiments on the amount of exhala-The latter found that a common Sun-flower, 3½ feet high, weighing 3 lb., with a surface of leaves equal to 5616 square inches, exhaled 20 ounces of liquid in the course of a day; a Cabbage plant, with a surface of 2736 square inches, was found to exhale, on an average, 19 ounces; a Vine of 1820 square inches, from 5 to 6 ounces; and a Lemon-tree of 2557 square inches, 6 ounces per day. He remarked that Evergreens exhaled less than plants with deciduous leaves, and he associates this with their capability to endure the cold of winter. The exhalation from leaves, according to Henslow, depends chiefly upon the effect of light on the vital energies of the plant.

Garreau made a series of experiments on the exhalation of leaves, by enclosing a living leaf between two bell-jars, one applied to the upper, and the other to the under surface, and ascertaining the quantity of liquid exhaled, by means of chloride of calcium which absorbs water with great rapidity. He found that the exhalation from the lower surface of the leaf was usually double, and even triple or quadruple, that of the upper surface. The quantity of water exhaled has a relation to the number of stomata. The exhalation is greater at the line of the ribs, or at the part of the epidermis where there is least fatty or waxy matter. The secretion of this matter in abundance during the warm days of summer, may tend to prevent the plants being injured by rain and by the heat of the sun. By impeding exhalation, it tends to retain the moisture which is necessary for the functions of the leaves.

In some plants, when water is supplied abundantly, there is a sort of distillation of liquid from the leaves. Arendt noticed this in a stalk of the Nettle when immersed in water. The liquid passed upwards in the grooves on the upper surface of the petiole, followed the ribs of the leaves, and then dropped from the apex of the leaves. From the extremity of the leaves of Richardia africana (Calla æthiopica) a watery fluid has been observed to drop in considerable quantity. The amount varies at different periods of the day, being most copious after mid-day. It ceases with the development of the spathe and organs of reproduction. A similar watery secretion has been noticed in other Araceous plants, such as Arum, Colocasia, and a plant called Caladium distillatorium; the water in these instances flows from an orifice near the point of the leaf, upon the upper surface, in which terminates a canal running along the margin of the leaf, while smaller canals, running along the principal ribs, open into the marginal one. Williamson found that from each healthy leaf of the latter plant about half-a-pint of liquid dropped during the night. Water also half-a-pint of liquid dropped during the night. drops from the margins of the leaves of Canna indica, angustifolia, and latifolia. In the hollow leaves of plants, such as Nepenthes, Sarracenia, Dischidia, and Cephalotus, a quantity of watery exhalation accumulates. Voelcker analyzed the liquid in the pitcher of Nepenthes, and found it to consist of water, containing in solution malic acid and a little citric acid, chloride of potassium, carbonate of soda, lime, and magnesia.

The exhalation of watery fluid from the leaves of plants influences the climate of a country. Humboldt remarks, that plants exhale water from their leaves, in the first place, for their own benefit, but that various important secondary effects follow from this process. One of these is, maintaining a suitable proportion of humidity in the air. Not only do they attract and condense the moisture suspended in the air, and borne by the wind over the earth's surface, which, falling from their leaves, keeps the ground below moist and cool; but they can, by means of their roots, pump it up from a very considerable depth, and, raising it into the atmosphere, diffuse it over the face of the country. Trees, by the transpiration from their leaves, surround themselves with an atmosphere constantly cold and moist. They also

shelter the soil from the direct action of the sun, and thus Botany. prevent evaporation of the water furnished by rains. In this way they contribute to the copiousness of streams. When forests are destroyed, as they are everywhere in America by the European planters, with an imprudent precipitation, the springs are entirely dried up, or become less abundant. In those mountains of Greece which have been deprived of their forests, the streams have disappeared. The inconsiderate felling of woods, or the neglect to maintain them, has changed regions noted for fertility into scenes of sterility. The sultry atmosphere and the droughts of the Cape de Verd islands are attributed to the destruction of forests. Dr Cleghorn states, that in large districts of India, climate and irrigation have rapidly deteriorated from a similar cause, and that the government are now using means to avert and remedy the mischief. In wooded countries, where the rains are excessive, as in Rio Janeiro, the climate has been improved by the diminution of the trees. Gardner says, that since the axe has been laid on the dense forests surrounding the city of Rio Janeiro, the climate has become dry. In fact, so much has the quantity of rain diminished, that the Brazilian government was obliged to pass a law prohibiting the felling of trees in the Corcovado range. Müller states that the cultivation of grain, which has so completely transformed one part of the wilderness of Australia, has already exercised a most beneficial influence on the increase of rain.

It is necessary to keep up the correspondence between the fluid given off by the leaves and that taken up by the roots. If the former exceeds the latter, the leaves become languid and fall off. This is one cause why plants growing in the rooms of dwelling-houses succeed badly. The atmosphere is too dry, and the exhalation from the leaves is not compensated by the fluids taken up by the roots. This cannot be remedied by an extra supply of water, for the roots are not capable of taking up the additional quantity required. Hence the use of Wardian Cases in preventing the loss caused by transpiration, and thus enabling the plants to live even in a warm and dry room.

b. Exhalation of Gaseous Matter.—Vegetable Respiration.

The leaves of plants give off gases, the nature and quantity of which vary according to the circumstances in which the plants are placed, and their state of vigour or decay. Hence leaves produce important effects on the atmosphere, and we shall find that they are employed as the means of keeping up its purity. In the year 1771, Priestley observed that plants were able to grow in air vitiated by the breathing of animals, and that they soon restored such air to its original purity. Percival confirmed these observations, and showed that air containing so much carbonic acid as to prove destructive to animal life, was rendered fit for respiration after plants had grown in it.

Ingenhousz examined the subject more fully, and made an extensive series of experiments. In air that had been so far depraved by respiration as to extinguish a lighted candle. he placed a plant of Peppermint, and then exposed the vessel for three hours to the sun, at the end of which time the air again supported flame. When a Nettle was put into a similar portion of impure air during the night, the air was not improved; but when exposed to the sun for two hours, its original purity was restored. Such was also the case with plants of Mustard. When similar portions of the same impure air were confined in vessels with similar plants, and respectively placed in sunshine and shade, the air exposed to the sun recovered its purity in a few hours, while that in the shade continued impure. Ingenhousz also per-formed experiments with immersed leaves, and found that they purified the air in the course of a very few hours in sunshine

Botany.

Senebier also instituted a series of experiments which proved the production of oxygen gas by plants exposed to the direct rays of the sun. He considered the oxygen as derived from the decomposition of carbonic acid; and he thought that plants in a healthy stated on ot give out carbonic acid in darkness. Ellis, De Saussure, Daubeny, and others, have corroborated these statements more or less fully. Aquatic plants appear to surpass all others in their power of decomposing carbonic acid. In some lakes in volcanic countries, where carbonic acid rises in great quantity through the water, vegetation is very vigorous, and the separation of oxygen goes on rapidly. Schleiden mentions that there is a rich vegetation round the springs in the valley of Göttingen, which abound in carbonic acid.

Physiologists still differ in regard to the actual amount of change produced in the air by leaves during the performance of their functions. Some maintain that oxygen is given off by the leaves during the day, and a moderate quantity of carbonic acid is exhaled by a process of endosmose during night; others say that carbonic acid is exhaled by plants in greater or less quantity at all times, and that during the day it is decomposed so as to give out oxygen; while a third set of authors state that no carbonic acid is evolved by leaves in a healthy state, and that their true function is one of deoxidation, or rather decarbonization, which consists in the fixation of carbon and the elimination of oxygen.

The first of these views was for a long time generally adopted, but some recent experiments have tended to throw doubts upon it, and to confirm the views of Senebier. Mohl still supports this view. He says plants have a double respiration—one consuming carbonic acid and exhaling oxygen by day in the green-coloured organs, and one connected with a consumption of oxygen and a formation of carbonic acid in the green organs by night, and in those not green, by day and night. If we wish to speak of a respiration in plants, he says, this oxygen-consuming breathing deserves the name far more than the exhalation of oxygen by the

green organs connected with the nutrient processes. The second view was propounded by Burnett, who considers the constant exhalation of carbonic acid both by day and by night as true vegetable respiration, while the decomposition of carbonic acid during light, accompanied with the evolution of oxygen, is regarded by him as a process of digestion; respiration thus going on at all times, and consisting, like that of animals, in the separation of carbon, while digestion only goes on during light. He has been supported by Carpenter, who says that the respiration of vegetables is not an occasional process, but one which is constantly going on during the whole life of the plant-by day, by night, in sunshine, and in shade—and consists in the disengagement of the superfluous carbon of the system, either by combination with the oxygen of the air, or by replacing with carbonic acid the oxygen that has been absorbed from it. If the function is checked the plant soon dies, as when placed in an atmosphere with a large amount of carbonic acid, and without the stimulus of light which enables it to decompose the acid gas. Garreau has also recently adopted these views. Henfrey says a distinction is to be drawn between the process of respiration in which the liberation of superfluous oxygen takes place, leaving the other elements combined in an assimilated or organic condition, and that process in which the assimilated matter is again chemically altered by the oxidation of a certain amount of carbon, which is liberated as free carbonic acid by plants unprovided with leaves, but under most circumstances decomposed again by green plants. He thinks that carbonic acid is given off by living plants as a vital process even during light, and he suggests that the re-absorption of the evolved acid gas during the day has disguised the fact in most previous experiments.

The third view of vegetable respiration has been brought Botany. prominently forward of late years by Mr Haseldine Pepys. From careful experiments, conducted during several years, he is satisfied that leaves which are in a state of vigorous vegetation, always operate so as to keep up the purity of the air, by absorbing carbonic acid, and disengaging oxygen; that this function is promoted and accelerated by the action of light; that it continues during night, although more slowly; and that carbonic acid is never disengaged when the leaf is healthy. He also finds that the fluid abundantly exhaled by plants during their vegetation is pure water, and contains no carbonic acid; and that the first portions of carbonic acid gas contained in an artificial atmosphere are taken up with more avidity by the plant than the remaining portions. The giving out of carbonic acid by leaves is attributed to disease, or to a change in the healthy state of the tissues; and in many experiments, the abnormal condition of the plant may perhaps account for the appearance of carbonic acid. In some of Mr Ellis's experiments, the decaying condition of the leaves gave rise to a fallacy in the re-Cloez and Gratiolet confirm Pepys' observations. They state that oxygen is disengaged rapidly in solar light, insensibly in diffused light, and not at all in darkness, and that in the latter case no carbonic acid whatever is given off by plants.

From all that has been stated, it would appear that an absorption of carbonic acid by the leaves of plants and an elimination of oxygen takes place during daylight, and that this process ceases in a great measure during the night. The exhalation of carbonic acid by healthy leaves is still doubtful, and the appearance of this acid gas may in many of the experiments be traced to an abnormal condition of the leaves. The great function of the leaves thus seems to be deoxidation, by means of which they are instrumental in keeping up the purity of the atmosphere. This function of plants is antagonistic in its results to animal respiration; for while the latter takes oxygen from the atmosphere, and replaces it by carbonic acid, the former removes carbonic acid, fixes carbon, and gives out oxygen. The processes of respiration and combustion are pouring into the atmosphere a large quantity of carbonic acid gas, while the active leaves of plants are constantly removing it, and, under the action of light, substituting oxygen. While plants thus get carbonaceous food, the air is by them kept in a state fitted for animal life.

As the decomposition of carbonic acid is only carried on vigorously during the day, it follows that an accumulation of it will take place in the atmosphere during darkness. Saussure found, from a mean of fifty-four observations made in a country district, that the proportion of carbonic acid in the atmosphere during the night was to its proportion in the day-time as 432 to 398; or in other words, the carbonic acid in the atmosphere was diminished nearly 10 per cent-during daylight. It is said also that during summer, when animal life is more active, the proportion of carbonic acid is greater than in winter, as 7.13 to 4.79 parts in 10,000. The usual quantity of carbonic acid in the atmosphere, before being drawn into the kungs, is about 1-2500th; in that returned from the lungs it is about 1-25th, or it has increased 100 times in quantity. So long as plants are kept in a vigorous and healthy state, they do not give off any carbonic acid. If, however, they are kept long in the dark they begin to fade; the green colouring matter called chlorophyll is not produced as it ought to be; the plants are blanched or etiolated, and in fact get into a state of disease. In such circumstances no oxygen is given off, but, on the contrary, carbonic acid is produced.

Experiments have been made by Draper as to the particular rays of the spectrum which are concerned in the decomposition of carbonic acid by the green parts of plants. They were made with a series of tubes half an inch in

Botany. diameter and six inches long, which were arranged so that the coloured spaces of the spectrum fell on them. In these tubes water impregnated with carbonic acid and a few green leaves of Poa annua were placed. In the tube that was in the red space a minute bubble of gas was sometimes formed, sometimes none at all; that in the orange contained a considerable quantity; in the yellow ray a very large amount was found, comparatively speaking; in the green a much smaller quantity; in the blue, indigo, and violet, and the extra-spectral space at that end, not a solitary bubble. Hence he drew the conclusion that the light-giving rays and those nearest the yellow have the greatest effect in the decomposition.

It has been stated that plants, when blanched, give off carbonic acid. Morot says that in partially etiolated plants, when exposed to the direct rays of the sun, the yellow portion of the tissue gave out carbonic acid, while the green parts gave out oxygen. Plants having no green leaves exhale carbonic acid. Thus Lory found, from thirty experiments, that Orobanches in every stage of their growth, whether exposed to light or not, absorb oxygen and give out carbonic acid. Lory took two parts of the same weight, one of Orobanche Teucrii, and the other of the leafy stalk of Teucrium Chamædrys, on which it was parasitic, and placed them in two jars of the same capacity, filled with six volumes of air to one of carbonic acid. Both were exposed to light from 9 A.M. until 3 P.M. of the succeeding day, and at the end of that time the air in which the Teucrium was placed contained no trace of carbonic acid, while that in which the parasitic Orobanche was placed yielded a large quantity of carbonic acid and a diminished amount of oxygen.

3. Influence of Leaves on Vegetable Secretions.

By means of the processes of absorption and exhalation which are carried on by leaves under the influence of air and light, the contents of the cells and vessels are elaborated and fitted for the production of various important secretions. To the action of the leaves must be traced in a great measure the elaboration of the azotized and unazotized compounds, to which allusion has already been made. When the functions of the leaves are interrupted by non-exposure to light, or by the attacks of disease, and when plants are deprived of their leaves by injuries of various kinds, their secretions are either wholly stopped, or they become altered in their nature. When leaves are blanched by being excluded from air and light, they lose their properties, their fragrant oils and resins are not developed in a proper manner, chlorophyll is not formed, nor is woody matter produced. Potatoes grown in the shade become watery, and produce little starch in their tubers.

The importance of leaves in the production of timber is universally acknowledged. If they are prevented from performing their functions properly, by being kept in darkness or in the shade, wood is imperfectly formed; and if the leaves are constantly stripped off a tree, no additions are made to its woody layers. Some troublesome weeds with underground woody stems may be enfeebled and ultimately extirpated by repeatedly cutting off their whole foliage. The difference of the wood in crowded and properly thinned plantations, depends in a great measure on the growth and exposure of the leaves. Wood grows more rapidly, and the zones or circles are larger, when there is free exposure. Hence the necessity of judicious planting if we wish to have good timber. When a tree forms large circles of woody matter, and thus grows rapidly, it has been found that the quality of the timber is better than when the same species forms small circles and grows slowly.

While in the cultivation of trees, shrubs, and ordinary flowering plants, the object of the gardener is to allow the

leaves to perform their functions perfectly, there are certain Botany. cases in which he endeavours to interrupt these functions, and to produce an unnatural condition, by which the plants are rendered more suitable for domestic purposes. All are familiar with the fact that blanching deprives the leaves of their green colour, and prevents them from acquiring their usual qualities. This depends on the effect of darkness in arresting the formation of chlorophyll or the green colouring matter, and in hindering the production of various secretions. In the case of Asparagus and Sea-kale, gardeners succeed by artificial etiolation (blanching) in preventing the plants from producing woody tissue—cells and thin-walled vessels being alone formed, which are delicate in their texture. The tenderness and succulence of the heart of the cabbage are due to the outer leaves obstructing the access of light. In Celery the effect of blanching is to deprive the plant not only of the woody tissue, but also of certain other secretions which render it in its ordinary condition unpalatable. It is thus distinctly proved that leaves owe their green colour to the action of light, and that it is only when light and air are supplied freely, that they can form the secretions which are required for the vigorous and normal growth of the plant.

4. Effects of Various Gases upon Leaves.—Wardian

In considering further the functions of the leaves, it is of importance to notice the effects produced upon them by different gases. The atmospheric air, with its oxygen, nitrogen, carbonic acid, and ammonia, is the gaseous mixture best fitted for the growth of plants. Certain gases in their unmixed state are poisonous to plants, while others do not seem to produce any deleterious effects further than the retardation of growth caused by the exclusion of atmospheric air. Saussure found that a plant of Lythrum Salicaria flourished for five weeks in hydrogen gas, and the Messrs Gladstone ascertained that nitrogen, oxygen, and nitrous oxide were innocuous. Plants would not of course continue to be vigorous in such atmospheres, inasmuch as they are deprived of the carbon which is necessary for them, and which can only be procured from carbonic acid.

Plants, when exposed to light, will thrive in an atmosphere containing a considerable amount of carbonic acid, but they cease to perform their functions in an atmosphere composed of carbonic acid alone. Daubeny found that Ferns and Lycopodiums, which are the plants most nearly allied to those of the coal epoch, can at the present day exist without injury in an atmosphere containing at least 5 per cent. of carbonic acid, and he thinks that this in some degree supports Brongniart's hypothesis as to the cause of the enormous production of carbon by the plants of that epoch. While plants in bright light can live in an atmosphere containing 5 to 10 per cent. of carbonic acid, Daubeny ascertained that the addition of a larger per-centage caused injurious effects.

In the atmosphere of towns, more especially those in which chemical and other manufactories exist, there are many gaseous and other matters present which interfere in a marked degree with the growth of plants. Every cultivator knows the difficulty of growing Roses and many valuable garden flowers in such situations. Drs Turner and Christison were led to examine the influence of gases on plants, on account of having been called upon to give evidence as to the effects of a black-ash manufactory on the vegetation in its neighbourhood. They found that many gases, even in minute quantity, injured and destroyed the leaves of plants, some of the gases acting as irritant poisons, others as narcotic poisons. The former destroyed the texture of the leaves and altered their colours, while the latter killed the leaves without producing any local effects on the textures. Sulphurous acid gas, which is very com-

Botany. monly met with in the atmosphere of towns was found to be exceedingly deleterious. Where four or even only two cubic inches were introduced, along with a young Mignonette plant, into the air of a glass jar, capable of containing 470 cubic inches, the leaves of the plant became greenishgray and drooped much in less than $2\frac{1}{2}$ hours; and, though then taken out and watered, it soon died altogether. In some of the experiments, the proportion of the acid gas was a ten-thousandth only, the quantity being one-fifth of a cubic inch, and yet the destruction of the leaves was complete in 48 hours. This proportion of the gas, although destructive to plants, is hardly or not at all discoverable by the smell. The effects of other irritant gases, such as hydrochloric and nitric acid, on the leaves of plants were also well marked. The former destroyed the whole vegetation of a plant of considerable size in less than two days, even when diluted with 10,000 parts of air.

Acid gases attack first the tips of the leaves and then extend to the stalks, and it is found that when the quantity is not great the parts not attacked generally survive, if the plants are removed into the air. Narcotic gases act very differently. Thus, Drs Turner and Christison found that $4\frac{1}{2}$ cubic inches of sulphuretted hydrogen in 80 volumes of air, in the course of 24 hours, caused several of the leaves of a plant to hang down perpendicularly from their stalks in a flaccid state, without injuring their colour; and though the plant was then removed into the air, the whole stem soon began to droop, and the plant died. When 6 cubic inches of the gas were mixed with 60 times their volume of air, the leaves began to be affected in 10 hours; they became quite flaccid, but did not appear changed in colour. When the leaves had once drooped the plants did not in any instance recover when removed into the air.

The effects produced by ammonia, cyanogen, carbonic oxide, and common coal gas, are in many respects similar to those now described, viz., a drooping of the leaves without alteration of colour, and the death of the plant even though removed into the air. The phenomena, when compared with what was observed in the instances of sulphurous and hydrochloric acid, would appear to establish, in relation to vegetable life, a distinction among the poisonous gases nearly equivalent to the difference existing between the effects of the irritant and narcotic poisons on animals. The gases which rank as irritants in relation to animals seem to act locally on vegetables, destroying first the parts least supplied with moisture. The narcotic gases, including under that term those which act on the nervous system of animals, destroy vegetable life by attacking it throughout the whole plant at once—the former probably only abstracting the moisture of the leaves, the latter acting by some unknown influence on their vitality.

The experiments just detailed show the importance of attending to the nature of the atmosphere in which plants grow. The blighting effects of the air of large cities are owing to the gases contained in the smoke, and unless means are taken for guarding against these, it is not to be expected that town vegetation can be luxuriant. The common gas used in houses is also prejudicial to vigorous growth, and this combined with the dry atmosphere of rooms is the cause of plants not succeeding well in private dwellings. The transpiration from the leaves in such circumstance is very great, and it is impossible to make the roots take up sufficient moisture to supply the loss. Hence the leaves fall off and the plants become sickly.

With the view of enabling plants to grow in the atmosphere of towns, notwithstanding the fuliginous matter and gases with which it is loaded, Mr N. B. Ward invented closely-glazed Cases, in which he succeeded in cultivating tender plants, even in one of the most populous and smoky localities of London. One of these Cases is represented in Figure 143. It consists of a strong box or trough, a, made

of well-seasoned wood, containing earth. The bottom of Botany.

the box is covered to a moderate depth with gravel and broken bricks, over which the soil is spread, composed of fibrous loam, sand, and peat. The nature of the soil may be varied according circumstances, and the box may be divided into compartments containing soils of different kinds. The soil is well watered, and the superfluous wa-

ter is allowed to run A Wardian Case, made by Messrs Drummond and freely from two holes Son, Canonmills, Edinburgh.

in the bottom of the box. After draining fully, the holes are tightly closed with corks, and the glazed roof or cover, b, is fitted on carefully in a groove round the upper part of the box. This glazed cover may be formed in various ways. It is frequently made of zinc, with large panes of glass, the upper one being curved.

Plants in these Cases are enabled to stand great changes of temperature without being injured, and they are protected from noxious matters in the atmosphere, besides having always sufficient moisture. Ferns and Lycopodiums, in an especial manner, succeed in such Cases. Those ferns which require much moisture and shade, such as Trichomanes radicans, can be grown successfully. The atmosphere, however, can be varied as regards moisture and dryness, and thus can be suited to different tribes of plants. The cases are well fitted for rooms or dwelling-houses, inasmuch as they prevent the excessive exhalation which so generally injures plants grown in these circumstances. The Cases have been applied most successfully to the transport of living plants, and many valuable productions have thus been introduced into different countries.

5. Coloration of Leaves.

The green colour of leaves depends on the production of chlorophyll, which is only developed under the agency of light. The leaves in the young bud are of a pale yellowish hue, and assume their green tint in proportion as they are exposed to light. The change of colour takes place more or less rapidly, according to the intensity of the light. The leaves of French Beans, which sprung white out of the earth, were observed by Senebier to become green in one hour under exposure to very bright sunshine. Plants, when grown in darkness, have pale leaves, which become green on exposure to light. It is said that an etiolated plant, when exposed to light, becomes green at the end of twentyfour hours, even under water. Diffuse daylight, and even the light of lamps, will cause a green coloration, but the intensity of the colour is much less than in full sunshine.

Experiments have been made in regard to the effects of the different rays of the spectrum in the production of the green colour of leaves. Senebier ascribed it to the violet rays, and Ritter and Wollaston to the chemical or tithonic rays, which are next the violet. Hunt thinks that the blue rays are the most active in this respect, while Morren, Daubeny, Draper, and Gardner, say that the yellow rays, or those having the greatest illuminating power, have the greatest effect in producing chlorophyll, as well as in deoxidation. The subject requires further elucidation.

In temperate climates the leaves during the period of

Botany. their diminished activity exhibit changes of colour which its natural state, but when it is in darkness, as well as when Botany. give rise to the yellow, brown, and red autumnal tints. These colours seem to depend on different states of oxidation in the chlorophyll. Hunt thinks that the brown colouring of the autumnal leaves is due to the rays called by Herschel parathermic, which can scarcely be said to have a defined place amid the calorific radiations, but which are usually most strongly manifested in the red rays. A slight tint of green was found to stop these parathermic rays, and on that account glass stained green with oxide of copper has been used in glazing the Palm-House at Kew.

Variegation in leaves is produced either by an alteration in the green chromule or chlorophyll, or by the presence of air in certain foliar cells. Sometimes a single group of cells contains the yellow product of the decomposition of the chlorophyll, as in Phalaris arundinacea picta, a variety which appears in a dry soil, and disappears in a wet one; or as in variegated varieties of Holly. At other times the epidermis separates itself from the cells lying under it in particular places, and the layer of air lying between these appears like a bright silvery spot, as in Begonia argyrostigma and Carduus Marianus. Treviranus states that in Monocotyledons the variegations form bands parallel to the veins; in Dicotyledons, such as Carduus Marianus, the white is produced in the veins, while in such as Aucuba japonica, the yellow spots are distributed without order. He states also that variegation is sometimes visible on the upper surface of the leaves, and not on the under. Variegation, according to Morren, has its seat deeper in the leaf than what is called spotting. The latter is confined to the cuticle or skin, while the former extends to the parenchyma or cellular tissue below.

6. Irritability and Contractility of Leaves.

Certain leaves display evident movements under the influence of light, heat, and a stimulus either of a mechanical or chemical nature. The effects of light and darkness are frequently very marked in causing the elevation and depression of leaf-stalks, and the expansion and folding of leaves. The changes which take place in leaves during darkness were included by Linnæus under what he called the sleep of plants. During darkness leaves often hang down, and, in the case of compound leaves, there is also a folding of the leaflets, either in an upward direction, as in the sensitive Mimosas, or downwards, as in Tephrosia caribæa.

Very obvious movements occur in the leaves of many species belonging to the natural orders Leguminosæ, Oxalidaceæ, and Droseraceæ. Among Leguminous plants may be noticed species of Mimosa, Robinia, Æschynomene, Smithia, Desmanthus, and Neptunia; in the family of Oxalidaceæ, many species of Oxalis exhibit a certain degree of irritability, but it is chiefly observed in the pinnate-leaved Biophytum sensitivum; while among Droseraceæ the leaves of Dionæa muscipula have a remarkable irritability, and those of the species of Drosera also exhibit traces of it. In some plants the movements are most marked in the young state. The movements exhibited by the leaves of plants may be divided into-1. Those which depend upon the periodical returns of day and night; 2. Those, which, besides being influenced by light and darkness, are also occasioned by any external or chemical agency; 3. Those independent, to a certain extent, of external influences.

In Mimosa pudica and sensitiva, which usually receive the name of Sensitive plants, the motions of the leaves are very conspicuous. They are influenced by light and darkness, and they are exhibited on the slightest touch. In these plants the leaf, as represented in Figure 144, is a compound bipinnate one, having four partial leaf-stalks proceeding from a common petiole. The small pinnules or leaflets are expanded horizontally when the plant is in the light and in

the leaves are touched or irritated, the pinnules fold upwards, so as to bring their upper surfaces into contact, and at length the petiole is depressed, so that the entire leaf falls down. When the whole leaves are thus folded and depressed the plant appears as if it were withered and dead. When light is introduced, or when the irritation is removed. the leaflets gradually unfold, and the leaf-stalk rises. In the ordinary state of the plant these motions go on daily. If two of the leaf-

Fig. 144. Branch and leaves of Sensitive plant (Mimosa pudica), showing the petiole in its erect state, a, and in its depressed state, b; also the leaflets closed, o, and the leaflets expanded, d.

lets at the extremity are touched, or are irritated by heat from a lens, or by electricity, without agitating other parts, they fold upwards, and a similar movement takes place in the adjoining leaflets in regular succession from the apex to the base of the petiole. The irritation is also communicated to the neighbouring partial petiole, the leaflets of which fold in a reverse order, namely, from base to apex. The movement may be propagated until the partial petioles converge and fall down; and, finally, the general leaf-stalk is depressed. If the lower leaflets are first irritated, the foldings take place from the base to the apex of the petiole; if the middle leaflets are touched then the foldings occur on each side. The stem itself seems not to be directly concerned in the motions. It may be injured in various ways without causing contractions to take place. A section may be made of it with a leaf attached, and yet the leaflets may remain expanded. Artificial light from six lamps, according to De Candolle, caused the expansion of the leaves; and Zantedeschi states that the lunar rays also affect the motions.

The action of the wind, or any general agitation, causes the simultaneous folding and depression of the leaves; but the quick repetition of an irritation exhausts the sensitiveness towards it. It appears that the plants may become accustomed to a weak stimulus. The more vigorous the plant, and the higher the temperature to which it is exposed, the more sensitive it is. The leaf of the Mimosa is sensitive of various kinds of stimuli, such as shaking, wounding, burning, contact of irritating fluids, electric and galvanic shocks. Many chemical stimuli cause the leaves to fold. Thus the vapours of prussic acid, of chloroform, and of ether,

Fig. 146. Fig. 145. Leaves of Venus's Fly-trap (Dionæa muscipula), which exhibit evident irritability. The leaf consists of two parts, a lamina or blade \(\), and a petiole or leaf-stalk, \(p \). The two halves of the blade are anited by a sort of hinge, \(a \), and there are on each of them three hairs, which, when touched, cause the folding of the laminæ in the way represented at \(\) and \(b \).

146. A portion of the branch and leaf of the moving plant of India (Bedysarum or Desmodium gyrans). The leaf is impari-pinnate, and often pinnately, trifoliolate. The large leaflet or pinna, \(a \), the smaller leaflets, \(b \), of which there are either one or two pairs.

are found to produce this effect; and in such cases the irri-

Botany. tability of the leaves is either destroyed, or, at all events, a considerable period elapses before it is restored.

The Yellow-water Sensitive plant (Neptunia plena), found in the East and West Indies and in South America, exhibits irritability in its petioles and leaflets. The leaves of Venus's Fly-trap (Dionæa muscipula), an American marsh plant, are provided with a jointed blade (Fig. 145), on each half of which are placed three hairs, with swellings at their base. When these hairs are touched or irritated in any way, the two halves of the leaves close. Flies and other insects are often found inclosed in the leaf, and hence the name given to the plant. It is said that the Sundews (Drosera) of our marshes also exhibit a certain degree of contractility, but this has not been distinctly proved. Their leaves (Fig. 107) are provided with viscid glandular hairs, to which insects are often found adherent, while the leaves are partially folded.

In the case of Hedysarum (Desmodium) gyrans, a native of the East Indies, the phenomena of leaf-motions are very remarkable. The leaf, as represented in Figure 146, is unequally pinnate, having a large leaflet or pinna α , at the extremity of the stalk, and two pairs of small pinnæ b, placed laterally. The large leaflet exhibits oscillatory lateral movements, as well as the ordinary sleep movements, in an upward and downward direction. During the day it rises and appears to have slow motion from one side to the other, so that it often is seen in an oblique position as regards the stalk; during the night it is depressed and motionless. The little pinnæ, on the other hand, constantly exhibit a jerking motion, by which they first approach to each other, and then retire, the length of time required to complete their movements being about three minutes when the plant is vigorous and exposed to bright light. The leaflets exhibit motions even in darkness, although to a less extent. Other species of Hedysarum exhibit similar movements.

The cause of these phenomena is obscure. Some have supposed that they are to be ascribed to the presence of a peculiar nervous system in plants. But there is no evidence of the existence of such a system, and the motions do not require that we should have recourse to such a theoretical explanation. All may be accounted for by changes in the contents of the cells. In the case of the sensitive Mimosas, there are evident cellular swellings at the base of the small leaflets, as well as the base of the petioles. These swellings, when touched directly, communicate motion to the leaves. They consist apparently of two kinds of cells, some of which display contractility, and others distensibility. When in their ordinary state these functions are balanced; but when mechanical or chemical stimuli are applied, a change in the cell-contents takes place, accompanied with a derangement of equilibrium. When the swellings at the base of the leaflets are touched gently on the superior surface, then the liquid contents of the upper contractile cells are sent into the distensible inferior ones, and the leaflets fold upwards. This change, however, is not effected by touching cautiously the lower surface of the swellings. Again, in the swelling at the base of the petiole, the reverse is the case, for there the lower cells are contractile, and the upper distensible, and the movement caused is in a downward direction. Touching the upper side of the intumescence at the base of the petioles does not give rise to the movement. If a portion of the lower side of the swelling is removed, then the balance between its resistance and the expansive tendency of the cells on the upper side is destroyed, and the petioles remain depressed. Any irritation applied to one part of the leaf is propagated by means of the vascular system to another part, and more especially it is communicated to the distensible portion of the cellular swellings just mentioned.

In the daytime, and under the influence of light, according to Fée, the fluids drawn to the surface of the plant are kept in equilibrium by rhythmical evaporation. There

is a constant renewal of fluids to supply those which have Botany. been transpired. A blow or wound, or the application of cold, interrupts the equilibrium, the circulation is deranged, and liquids pass quickly from the cells into the vessels, and thus cause distension. During the night the sap is feebly drawn to the surface, and thus a change takes place in the relative contents of the different cells and vessels. The phenomena are thus referred to changes in the fluid contents of the cells and vessels caused by certain vital actions. Mohl refers the movements partly to the distension of the cells, and partly to different states of tension in the tissues, and he considers the movement of irritability as not identical with the sleep movement. He says that the articulations are composed of numerous parenchymatous cells containing chlorophyll, each also exhibiting in its interior a larger or smaller globular mass of a substance strongly refracting light. The parenchymatous tissue, he says, exhibits a considerable distension. If a flat portion is cut longitudinally out of the middle of the joint, and afterwards this portion is cut lengthways into thin strips, the cellular tissue forming the sides of the strips immediately expands about one-fifth longitudinally, while the vascular bundle in the middle continues as before. Hence, he says, the vascular bundle appears to be too short in proportion to the turgescent mass of cellular tissue of the articulation, while the latter is compressed in the direction of the longitudinal axis in the uninjured part. In the ordinary state of the plant, the expansion of the cellular tissue of the upper side of the articulation maintains the equilibrium with the cellular tissue forming the under side, and thus curvation is prevented. But if the cellular tissue is cut away down to the central vascular bundle on the upper side of the articulation of a leaf still attached to the plant, the cellular tissue of the lower side having now lost its antagonist can pursue its expansion, and the leaf becomes at once pressed upwards at a sharp angle—the reverse occurring when the cellular tissue of the under side is removed.

In the case of Hedysarum gyrans and other species, the movements are probably referable to changes in the contents of the cells and vessels, not directly induced by mechanical irritation, and only partially influenced by the stimulus of light and heat. In Venus's Fly-trap (Dionæa muscipula) the irritation of the hairs is apparently communicated by means of vessels to the cells between the two halves of the leaf-blades, in such a way that distension takes place in the lower cells, and thus the leaves close. The object of these various movements is not known.

7. Defoliation, or the Fall of the Leaf.

Leaves continue to perform their active functions for a certain length of time, and are then replaced by others. In temperate climates these functions go on vigorously during spring and summer, but towards the end of autumn they become languid. In the ordinary trees of this country the leaves fall off during winter, a latent bud having originated in their axil whence new leaves arise in spring. In warm climates the dry season often causes a similar exuviation of the leaves. This is observed in the Brazilian forests called The times of the appearance and of the fall of the leaves vary in different countries, and from them may be deduced conclusions as to the nature of the seasons.

The fall of the leaf has not received the attention it deserves from physiologists. The reason frequently given for this phenomenon is the choking up of the cells and vessels of the leaf by deposit of earthy and saline matters, in consequence of the process of absorption in autumn not keep ing pace with the exhalation of watery fluid. There is no doubt that mineral substances do accumulate in the leaves in autumn, but there seems to be no proof that this is the sole cause of their fall. When autumn approaches, it

Botany. is found that a gradual separation takes place between the leaf-stalk and the stem or the axis to which it is attached. This is not a mere accidental occurrence, but is a process for which regular provision is made. According to Inman a process of disjunction goes on from the time the leafstalk is fully formed until the leaf has ceased to perform its

> In cold climates various causes operate in causing defoliation. As the light and heat diminish there is a cessation of the functions of cells and vessels, evaporation takes place from the surface, inorganic matters accumulate in the tissues, the leaf becomes dry, its attachment to the stem is loosened. and then it either falls by its own weight, or is detached by external agencies of different kinds. Dr Fleming states, that winter is not the immediate cause of defoliation. Many leaves fall before the approach of winter, others perish in spring. He divides trees in reference to the duration of their leaves into three classes:—1. Those in which the leaves cease to perform their functions when the bud is complete. 2. Those in which the leaves continue to perform their functions until new ones appear the following season. 3. Those in which the leaves continue to perform their functions for several years.

> The leaves of the first class are Deciduous, and they seem to be connected with the ripening of the bud. When this takes place, these leaves change their colour and perish. In Willows, even in midsummer, many of the branches become naked from the fall of such leaves. In trees having two evolutions of buds in the season, as the Beech, the leaves produced in spring fall sooner than those which are developed on the summer shoots. Leaves of the second class Dr Fleming calls Annual. These continue till new leaves are produced, and are cast off in the order of their development. In Evergreen trees and shrubs the leaves of one season continue their functions until those of the next season are produced. The leaves of the third class Dr Fleming calls Persistent. Their duration, does not seem to be regulated by the perfection of the bud, nor by the development of new leaves. They continue their functions for several years. This is the case with ordinary Evergreen Firs. In these plants the leaves of various years seem to be required for the complete formation of the stem and its secretions. On the same tree, may be seen leaves two, three, or more years old.

> The sap absorbed by the roots, and which contains various inorganic matters in solution, reaches the leaves, and is thus exposed to air and light. There is a large transpiration of watery fluid, and the inorganic matters not required for the organism and secretions of the plant are stored up in the leaves, forming at times incrustations on the walls of the cells. The quantity of ash left after burning leaves varies at different periods of the plant's growth. Vernal leaves contain a small amount of ash, while autumnal ones leave a large quantity when burned. The latter contain from 10 to 30 times more ashes than the wood of the same plant.

V .- GENERAL CIRCULATION OR MOVEMENT OF THE SAP.

Plants are not provided with a circulating system like that of animals, and they do not exhibit movements of fluids to and from a common centre. Liquids are diffused throughout the whole plant by the action of cells and vessels having a different chemical constitution and different functions. One cell takes the juice from another, and acts by diffusion on the others. The cells of the rootlets imbibe by endosmose fluid matters which are carried into the stem, and the cells of the leaves, by their exhaling functions, aid in promoting a general movement of sap throughout the whole

It is not easy to make experiments on the motion and course of the sap, both on account of the minuteness of the

vegetable tissues, and the unavoidable injury which must Botany. be inflicted on them in any attempt to observe these living ' actions under the microscope. We cannot, as in animals, put ligatures on vessels, nor by an injecting apparatus send coloured matters into them. Endeavours, however, have been made to trace the course of the sap by causing the roots to absorb solutions of substances which can be easily detected by chemical reagents at different parts of their progress. Thus a weak solution of acetate of lead has been employed, which can be detected by iodine, sulphuretted hydrogen, and other tests; also a solution of ferrocyanuret of potassium, which can be tested by chloride of iron, or by sulphate of the peroxide of iron. The last has been used recently by Hoffmann in his experiments, and he finds the blue colour produced by the action of salts of iron on the ferrocyanuret a good means of tracing the course of the sap. As the Prussian blue thus formed is insoluble in water, a little care in dissecting enables us to avoid the spreading of the colour to unaffected parts.

It may be remarked in general, in regard to these experiments, that very different results followed, according as the absorption took place by the uninjured roots, or by the cut surfaces of plants. In the latter instance, the fluids were found in vessels which they did not enter in the former case. In cellular plants the sap seems to move through all parts, and is not confined to any definite set of cells. In vascular plants it appears in general that the sap enters the cells and woody vessels (and perhaps the intercellular spaces); and that the spiral vessels and those allied to them, such as annular and scalariform vessels, very generally contain air when the sap enters slowly. But when there is a rapid movement of sap either from the root upwards or from the leaves downwards, especially in Dicotyledons, then the spiral vessels take up fluids as well as air. It seems probable that the spiral vessels and their allies are receptacles for gaseous matter formed in the course of the movement

In truly cellular plants, as Fungi, the course of the circulation has no accurately fixed boundaries, and presents no anatomical peculiarities. The fluid is found to proceed both forwards and laterally in the cells and intercellular spaces, proceeding most rapidly in those parts where the tissue is most lax. In plants such as Lichens, where the tissue is dense, and in which there is not much fluid, the sap passes with great slowness between and through the cells. In the case of mosses possessing leaves, the fluid was found to pass through the stem and fruit-stalk, and in the leaves it moved most rapidly in a peculiar layer of cells along their margin and not in the midrib. Probably the condensed cells and vessels of the midrib are concerned in the conduction of fluids from the leaves in a downward

In Ferns it was observed that the scalariform vessels and closed spirals contained air, and that they did not take up any of the solution of the ferrocyanide. If the petiole of the frond is cut across and inserted in the solution, then the latter passes into the scalariform vessels, driving out the air. The leaf of the Fern, when dipped in the liquid, absorbs it, but it does not pass into the scalariform vessels. In Ferns there did not appear to Hoffmann to be any path for descending juices, and this is probably connected with their mode of growth, which is by additions to their summit (acrogens). The streaked vessels in Ferns seem to be destined exclusively for gaseous matters, while the fluids absorbed from the earth first ascend within the loose cellular tissue in the vicinity of those vessels, and are from them diffused throughout the remainder of the tissues after suitable elaboration. In Monocotyledons the solution of the ferrocyanide ascended chiefly through the elongated cells surrounding the spiral vessels, and the latter contained, in ordinary circumstances, air in their interior.

Botany.

Botany.

In regard to the course of the sap in Dicotyledons, numerous experiments have been made. Walker, Burnett, and others made incisions into the bark and wood of trees in spring and summer, and marked the points where the sap made its appearance. In this way they endeavoured to trace the course of the fluids in the stem. Walker concludes, from his experiments, that the spring sap begins to flow at the root, that it ascends slowly upwards, and bleeds successively as it ascends to the very extremity of the tree; that there is no descent of sap until after the development of the leaves. Burnett cut notches in the trunks of various trees in spring, at different heights in each tree, from one to six feet from the ground; and in every instance the sap was seen distinctly exuding from the lowest side of the lowest section first, and progressively rising to the others day by day. The chief current was axial in the first instance, and afterwards the sap entered the branches. To the progress of the sap in the direction of the axis he attributes the early develop-ment and vigour of terminal buds. Mohl states that when a ring of bark is taken off, the flow of sap to the parts above it is not interrupted; but if a portion of the wood is carefully removed without injury to the bark covering it, then the portion of the plant above the wound dries up at once.

Hoffmann bored holes in the stems of trees, such as the Sycamore, and inserted quills with the inner ends cut off obliquely, and the orifices looking upwards—the quills being cemented in their place. He made experiments with the spring sap, by inserting the roots of plants in a solution of the ferrocyanuret of potassium, and testing the fluid at different heights as it was discharged in drops from the quills. He found that the exudation of the sap in spring occurred obviously earlier in the lower than in the upper part of the stem, and that the ascent of the fluid was confined to that side of the stem which corresponded to the absorbing root.

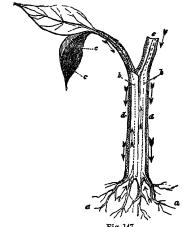

In spring, it appears that the sap, as it increases in quantity, besides filling the cells and vessels of the wood, also enters the spiral vessels. This is the time when the plant bleeds freely on being wounded. As the leaves expand, transpiration of fluids takes place, and then the spiral vessels contain air. In some climbing plants, this state of fulness in the spirals, as well as in the wood, continues permanently. After the leaves expand, in ordinary trees the conduction of sap takes place through the newer woody vessels and cells, and not through the fibro-vascular tissue. The circulation of the sap during summer, when the leaves are most active, differs from that in spring, in the circumstance that the trees do not bleed when wounded. In summer, as in spring, there exists a rapid ascent of crude sap; but in addition to this, there is a descent of the elaborated fluids from the leaves to all parts of the plant. Hoffmann states that there is also a descent of unelaborated fluids after every shower of rain.

Some authors believe that the chief channels by which the sap ascends are the intercellular canals, which are more or less continuous from one end of the plant to the other, and that from them it passes to the other parts, each cell and vessel taking from the general circulation what is required for its growth and nutrition. In this view the cells and vessels would be regarded as secreting organs, acting in various ways on the general mass of crude sap, and separating from it by a chemico-vital action different liquid and gaseous matters. The recent experiments of Hoffmann do not support this theory of sap movement, and the general opinion of physiologists appears to be that in its upward progress the sap passes through the newer pleurenchyma, as well as through the intercellular spaces, until it reaches the leaves, where it is elaborated. The different layers of wood convey sap in different quantity, the youngest being those chiefly concerned in the process. The conveyance of sap is not carried on by the old layers of wood when they become hardened by deposits. Hence trees with a large amount of hard wood, and a moderate quantity of sap wood, dry readily,

while trees, like the Birch, with a large quantity of alburnum, have sap movements even in the central layers of wood.

While such is the way in which the sap of Dicotyledons ascends, it is not easy to trace the mode of its after-diffusion. The usual opinion is, that after undergoing changes in the leaves and other green organs, it descends in the direction of the bark, and is thence conveyed to all the active cells and vessels of the stem. Experiments similar to those already detailed were made by Walker and Burnett as to the descent of the sap. When incisions were made in the bark, after the sap had reached the leaves, it was found that the upper portion of the cut was first moistened apparently by liquid from the upper part of the stem. If a complete ring of bark is cut off, then the growth of the portion below the wound ceases, the thickness of the stem is not increased, and, in the case of the potato, according to Mohl, no tubers are formed. At the same time the part of the stem above the wound increases much, and, in the case of trees, a thick layer of wood is formed. It would thus appear that there is a descent of elaborated sap from the leaves towards the bark, and that from this it is diffused through the rest of the tissue. Rainey thinks that the descent is through the vessels, and not the cells nor intercellular spaces; and Schultz considers the laticiferous vessels as those through which the elaborated sap descends.

Thus, as represented generally in Figure 147, the sap in

Ideal section of the stem of a Dicotyledon, showing the general course of the sap, as indicated by the arrows. The roots, a, absorb liquids, which pass through the newer pleurenchyma and intercellular spaces, b, reach the leaves, c, c, and after elaboration descend towards the outer part of the trunk, d, whence they are diffused in various directions; c marks the section of a branch.

a Dicotyledonous tree describes a sort of circle not in determinate vessels, but by a definite path, through different parts of the plant; passing upwards from the roots, a a, through the newer woody tissue, bb, reaching the leaves, cc, and after elaboration descending towards the exterior of the trunk, d d, whence it is diffused in various directions, both internally and externally. An absorption of water, containing various matters in solution, is constantly going on through the extremities of the rootlets. This crude sap is carried forward through the cells, vessels, and intercellular passages, by a force which acts by propulsion. The stimulus of light, acting on the cellular tissue of the leaves, or on green stems when no leaves are present, enables these parts to elaborate the organic compounds which are necessary for vegetable nutrition. The leaf-action may be reckoned one of at traction or suction. The diffusion of the elaborated matters constitutes the descent of the sap. Gaseous matters are also carried up with the sap.

Various causes conspire in originating and keeping up the movement of the sap. During winter, when vegetation is arrested, the cells of perennial plants are filled with albuminous and starchy matters. The conversion of starch into

CXXXV.

I.-ANATOMY OF THE REPRODUCTIVE ORGANS.

I.—REPRODUCTIVE ORGANS OF FLOWERING PLANTS.

The flower or Floral organs concerned in the production of seed, containing the young plant, are called Organs of Reproduction. In Dicotyledons and Monocotyledons they are usually obvious, and hence these plants are called Phænogamous or Phanerogamous (φαίνειν, to show, or φανερός, conspicuous, and γάμος, marriage), while in Acotyledons they are obscure, and hence the plants are called Cryptogamous (κρυπτός, concealed, and γάμος, marriage), the former being Flowering plants, the latter Flowerless.

1. The Inflorescence.

This term designates the arrangement of the flowers on the flowering stem or branch. Flowers are produced from flower-buds, as leaves are from leaf-buds. These two kinds of buds have a resemblance to each other as regards the arrangement and the development of their parts; and it sometimes happens, from injury and other causes, that the part of the axis which, in ordinary cases, would produce a leaf-bud, gives origin to a flower-bud. It will be afterwards shown that. morphologically considered, the flower is to be looked upon as a shortened branch bearing parts analogous to leaves. The flower-bud contains either one or many flowers.

Bracts.—Like leaf-buds, the flower-buds arise either from the extremity of an axis, and are then terminal, or they are produced from the axil of leaves called Bracts. These bracts are sometimes like the ordinary leaves, as in many species of Speedwell, Periwinkle, and Pimpernel, where they bear single flowers, and in the common Bugle, Dead-nettle, and some species of Veronica, where they produce several flowers. They have the colour of leaves in such instances, and consist of cells and vessels, similarly arranged, in the form of parenchyma, ribs, and veins, with epidermis and stomata.

Bracts, however, in many plants, as regards colour, size.

and form, present a different appearance from leaves. In Amherstia nobilis, and in some species of Salvia, they are large, and of a fine scarlet colour, so as to give a marked character to the flowers. In Palms, and in species of Arum,* the bracts are large and sheath-ing, and are called Spathes; they inclose numerous flowers, supported on a common succulent stalk, called a Spadix. In some South American Palms, such spathes inclose upwards of 200,000 flowers, and they are sometimes

sheathing bracts are seen. In Grasses, the bracts constituting the outer covering of the spikelets of flowers are called Glumes (Fig. 150, gl).

In the case of numerous flowers on a common stalk, the bracts are often numerous also, and are arranged in a whorl or *Involucre*, as it is called. An assemblage of involucral bracts, called phyllaries, is seen in composite flowers, such as *Plate the Daisy, Dandelion,* and Marigold (Fig. 151), and in CXXIV. Umbelliferous plants, such as Hemlock.* In some Umbelli-*Pl. CXX.

Botany. sugar in spring will at once determine an endosmotic action in the cells. The cells of the root, with their delicate walls, allow the fluids from the roots to pass readily by imbibition. A physico-chemical endosmotic action takes place, by which the fluid is propelled upwards. As the sap is constantly parting with its fluid contents, more especially when it reaches the leaves, the fluid in the upper cells is thickened, and consequently the thinner fluid below passes in by endosmose. In addition to this, there are vital actions going on in the cells and vessels, which give rise to a constant in-

terchange of ingredients.

Schacht says the property which certain cells have of absorbing and elaborating one substance more abundantly than another, produces an ascending and a descending current. It is possible that each cell may direct the substances it holds in solution upwards, laterally, or downwards, according to the demands of the neighbouring cells. The current of sap will consequently be directed according to the wants and the degrees of vital activity of cells having different functions. The active processes of cell-formation going on at the extremity of the stem powerfully promote the ascent of nutritive juices. As the cambium of the vascular bundles extends from the extremity of the root to the apex of the stem, there is a constant transmission of fluids from cell to cell. As new cells are constantly formed at the extremity of the stem, by means of which azotized and other matters are consumed, there is a constant demand for a supply from below. exhalations going on in the leaves naturally give rise to a constant flow of fluids to supply the place of those which have been carried off. The capillary action of the intercellular canals may also aid in the movement, in proportion as watery fluid is removed from their extremities.

The various physical, chemical, and vital causes operating in the movement of the sap may be thus enumerated: Endosmose acting as a vis a tergo or propelling power,

and commencing in the cells of the root; chemico-vital actions causing changes in the contents of the cells and vessels; capillarity in the intercellular canals; and a vis a fronte or attracting power depending on the transpiration from the leaves. Heat and light materially promote the movement of the sap.

The force with which the sap ascends in the stem was measured by Hales by means of an apparatus such as is represented in Figure 148. A bent tube, f d b, was firmly attached to a stem, a, the top of which had been cut off, and the force of the sap was estimated by the rise of the mercury previously introduced into the tube, so as to fill the curvation between e and f. The force of the sap in one experiment was equal to 38 inches of mercury, which Hales states is nearly five times greater than the force of the blood in the crural artery of a horse, and seven times greater than the force of the blood in the crural artery of than the force of the blood in the crural artery of a does not find the crural artery of the blood in the same artery of a does not find the same artery of a does not find the carrier of a does not

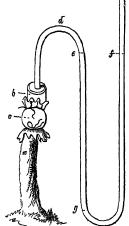

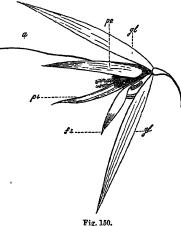

Fig. 148.

than the force of the blood in the same artery of a dog. Brucke found that in a Vine, the spring sap, having a specific gravity of 1 0008, raised a column of mercury to the height of $14\frac{1}{2}$ inches, and therefore exerted a pressure equal to that of a column of water 195 inches high. In another experiment sap of specific gravity 1.0009 raised the mercury to the height of 172 inches.

Rotany. feræ there are two rows of bracts in each head of flowers. -one, denominated the general involucre, at the base of the large umbel; the other the partial involucre, or involucel, at the base of the smaller umbels, or umbellules. *Pl.CXIX. In Fool's Parsley* (Æthusa Cynapium), the involucre consists of three deflexed leaflets. The bracts connected with the

flowers, in the catkins of the Poplar, of the Willow, the Walnut, and other amentiferous (catkin-bearing) plants, are called Scales.

Bracts sometimes fall off when the flowers expand; at other times they continue during flowering, and, in certain instances, they form part of the fruit. The cup (cupula) of the Acorn (Fig. 152, a), and the husk of

the Hazel-nut, are formed by bracts; So also are the flower. Spikelet of Oat (Avena satura) laid open, showing the bracts, gl, gl, which are denominated Glumes; pl, the outer pale or glumellule, with a dorsal amm, apl, pl, the inner pale; fs, an abortive flower.

scales of the Hop-fruit, of the Fir-cone, and of the Pine-

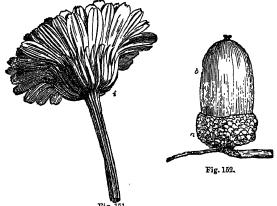

Fig. 151. Head (Capitulum) of Marigold (Calendula), showing a congeries of flowers, inclosed by rows of bracts or phyllaries, i, at the base, which are collectively called an Involucre.

152. Fruit of the Oak (Quercus pedunculata), showing a collection of bracts, a, forming the cup (cupula) of the acorn, b.

Bracts are said to be *empty* when they do not give origin to flowers. Thus, in Salvia Horminum, the top of the flowering axis ends in a series of coloured empty bracts, and in the Pine-apple plant the fruit is terminated by a crown of leaves, which are to be considered as empty bracts, terminating the axis. The outer row of scales in the involucre of some compound flowers consists of empty bracts, which occasionally produce buds, as in the case of the Hen-andchickens daisy. In Cruciferous plants, such as Wallflower, and in the Borage tribe, such as Forget-me-not, bracts are very rarely developed, and hence they are called ebracteated.

When an axis bearing numerous stalked flowers arises from a bract, there are sometimes smaller leaves, called Bractlets or Bracteoles, at the base of the small flowerstalks. When bracts or bractlets are placed, so as to be close to the outer envelope (calyx) of the flower, there is occasionally some difficulty in determining what parts are to be referred to each of these organs. In the Mallow tribe the outer calyx (epicalyx) seems to be of this nature. When bracts adhere to the flower-stalk and become decur-

rent, as in the Lime-tree (Fig. 153), they appear like Botany. winged branches, giving origin to the inflorescence.

Flower-stalk.—The axis bearing the flower or flowers is called the floral axis. It is a branch coming from a flower-bud. The term Peduncle is that usually given to a

stalk supporting a single flower, or numerous flowers, which are either sessile (applied closely to the peduncle) as in the catkin, or are placed on stalks called Pedicels. When the peduncle proceeds in a straight line from the base to the apex of the whole inflorescence, it is often called the Rachis, or axis of inflorescence. A peduncle arising from a stem, either subterranean or close to the ground, and bearing a solitary flower, as in the Primrose, or bearing nu-

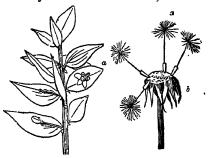

merous stalked (pedi-cellate) flowers, as in the Cowslip, Narcissus (Fig.

149), or numerous sessile flowers, as in the Daisy and Dandelion, is called a Scape or Radical peduncle. In the female flower of Vallisneria (Fig. 22, b), the scape is spiral, and uncoils, so as to allow the flowers to appear above the surface of the water in which the plant grows.

The peduncle is usually rounded like a branch, but this

is by no means its invariable form. Thus, in various species of Butcher's - broom (Fig. 154), and Epiphyllum, it is a broad leaf-like (phylloid) expansion. In the Cashew-nut* the pedicels supporting single flowers beshortened and

*Plate CXVI.

single flowers become succulent, and are used as food. When the peduncle bears numerous flowers, in place of being elongated, it sometimes is shortened and comes slightly convex.

thickened, especially at its apex, so as to form a broad flattened disk, as in the Thistle and Dandelion (Fig. 155), a conical projection, as in the Daisy, a concave surface, as in Dorstenia (Fig. 156), or a hollow fleshy pear-like body, as in the Fig (Fig. 157). The peduncle is transformed, in some instances, into tendrils or spines, at other times its apex is hollowed out, so as to form part of the calyx, as in Eschscholtzia,* or of the fruit, as in Hovenia. Flower-stalks, bearing hairs in place of flowers, occur in the Wig-tree (Fig. 158).

The arrangement of the flowers on the peduncle or floral axis exhibits considerable variety. The simplest kind of inflorescence (floral arrangement) is that in which single flowers are supported on flower-stalks, as is seen in the Gentianella, and in the common Periwinkle, the Pimpernel, and Fumitory. In these instances there is a difference in the

CXIII. fig. 7.

Botany. mode of floral development. In the Gentianella (Fig. 159) when the floral axis elongates, they form a raceme. If the Botany

F1g. 156.

Fig. 157.

Fig. 158.

the flower, b, with two leaves at its base, terminates the general or primary flowering axis, a; in the Fumitory (Fig. 160) the floral axis elongates,

producing leaves, while the flowers are borne on secondary axes or stalks, which are axillary and lateral. In the former case the axis is arrested in its growth, and the inflorescence is Definite or Determinate; in the latter the axis is progressive, and the inflorescence is Indefinite or Indeterminate. These plants illustrate, in their simplest forms, two marked forms of Inflorescence, which it is necessary to bring more fully under notice.

Indeterminate or Indefinite Inflorescence.—The simplest form of this inflorescence is that in which the flowers arise singly from the axil of ordinary leaves, which, in this instance, serve the purpose stance, serve the purpose of bracts, while the axis goes on elongating and bearing leaves at its apex. In place of a single flower, however, there are frequently several flowers produced on a floral axis in this kind of inflores-

cence; as is seen in some species of Speedwell, in which there arises from the axil of a bract a cluster of flowers expanding in an ascending series from below upwards. As the flowers in the indefinite inflorescence are produced like buds in the axils of leaves, they are denominated Axillary; and, when numerous, they follow the ordinary law of leaf development —the lowest (i. e., those next the primary axis), expanding first when the floral axis is elongated (Fig. 160), or the outermost when the axis is depressed or abbreviated (Fig. 151). The expansion of the flowers, in such cases, is denominated Centripetal, in consequence of proceeding in a progressive manner towards the centre or apex.

Axillary flowers, on elongated and shortened axes, present different forms of inflorescence, according as the flowers are stalked or sessile, the stalks simple or branched, and equal or unequal in length. When the primary floral axis (peduncle or rachis) lengthens and bears equally stalked (pedicellate) flowers, each originating from a bractlet, a Raceme is produced, as in the Hyacinth, Currant, and Fumitory (Fig. 160). In this instance, the lowest flowers, i.e., those next the primary axis, are first expanded, and the others follow in succession from base to apex. When the raceme has the lower flowers supported on longer stalks than the upper, in such a way that all form nearly a level top, as in the Hawthorn, and some species of Cerasus (Fig. 161), a Corymb is formed. In Cruciferous plants the flowers, when first produced, frequently appear as a corymb, and

Fig. 159. Fig. 160.

Fig. 159. Flowering stem of Gentianella (Gentiana acaulis). The plant produces a single flower, and it is called uniforal. The termination of the axis, n, bears two leaves or bracts. c. The flower, b, with its calyx and corolla, terminates the axis. This is the simplest form of definite inflorescence. If other axes are produced in such a case, they arise from the axil of the bracts, c. and the flowers expand after the central one, b, or in what is called a centrifugal manner.

Each axis ends in a solitary flower.

... 160. Peduncle or floral axis of Funitory (Fumaria officinalis), bearing numerous flowers (multifloral). Each flower is attached to the rachs or floral axis by a short stalk called a pedicel, arising from a small floral leaflet or bractlet.

primary axis of a raceme is shortened, so that the floral stalks all proceed from apparently the same point, form-

ing nearly equal radii, as in the Cowslip, an Umbel is produced. In the indefinite umbel, the outermost flowers, i.e. those of the circumference, expand first. The simple Raceme, Corymb, and Umbel, may become compound by the stalks of the flowers branching. In the case of the umbel, the branching takes place by the secondary stalks coming off from a point like radii of a circle, in the same way as the primary ones did (Fig. 162). When bractlets occur at the base of the primary stalks, or, in other words, at the base of the primary umbel, they are arranged in a whorled manner, and form an Involucre, and such is also the case with the bractlets at the base of the secondary flowerstalk or secondary umbel. The secondary, or partial umbels,

are called Umbellules, and the verticillate bractlets* receive the name of Involucel. In some instances, as in Fool's Parsley, there is no general involucre, but simply an involucel (Fig. 163, b b); while, in other cases, as in Fennel, neither involucre nor involu-

Fig. 161.

Simple indefinite corymb of a kind of Cherry (Cerasus Mahaleb). A multiforal peduncie, p, arises from a bract, and bears pedicellate flowers, the lower pedicels being longer than the upper, so that the flowers form nearly a flat surface above. The lowest flowers expand first, and hence the order is centripetal.

*PLCXX

Fig. 162.

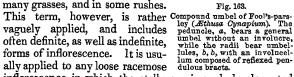

cel are developed.
Compound umbels are frequent in

Botany. *Plate

CXX.

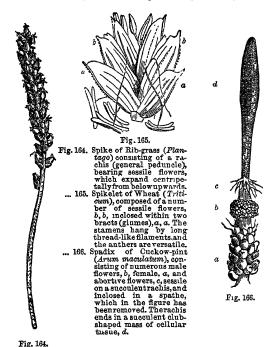

Umbelliferous plants, such as Hemlock, * Carrot, and Parsley.

In compound inflorescences there occurs a combination of these forms. Thus, the primary divisions may be racemose, or cofymbose, or umbellate, while the secondary are of a different nature. A raceme in which the secondary branches assume the form of a corymb, or a corymb in which the secondary branches are racemose, is called a Panicle, a form of inflorescence met with in many grasses, and in some rushes.

inflorescence in which the stalks are irregularly elongated and branched. When the panicle is shortened, as regards its secondary branches, and forms a compact cluster resembling a bunch of grapes, as in Lilac and Horse-chestnut, it is called a Thyrsus.

In the instances of inflorescence which we have noticed, the flowers are all supported on stalks either of the same or different lengths. When the flowers are sessile, i.e., without stalks, different forms of the indefinite inflorescence arise. A raceme, with sessile flowers, becomes a Spike, as in Plantago (Fig. 164). In grasses the flowers are arranged in small spikes called Spikelets (Locustæ), as seen

in Figure 165, and these spikelets are themselves arranged either in a panicled form, as in Oats, or in a spiked form as, in Wheat. The latter may be called a compound spike, consisting of a series of small spikes sessile on a common rachis. Occasionally, as in Egyptian wheat, several compound spikes proceed from the top of the stalk or culm. A Spadix is a succellent spike, inclosed in a sheathing bract called a Spathe, as in the Cuckow-pint* (Fig. 166), and Æthiopian Calla, where it is simple, and in Palms, where it is branching and compound. A Catkin, or Ament, is a

167), the Walnut, the Hazel, the Birch, the Poplar, and in many other trees which are hence called Amentiferous. Catkins bearing sterile flowers only, generally fall off early, and in one piece. Some restrict the term catkin to such deciduous forms of inflorescence; while others include also the fertile scalv spikes of Hazel, of Birch, and of Willow. The catkin is sometimes branching, i.e., produces numerous separate catkins on a common axis, as in the male flowers of the Fir. The Cone of the Pine, Spruce, Fir, and other cone-bearing plants, is a female spike of flowers with hard scales covering naked seeds, while the Strobilus of the Hop is a similar kind of spike with membranous

of the fruit.

spike having scaly bracts. It occurs in the Willow (Fig. Botany.

Fig. 167. scales covering seed-vessels. Catkin (Amentum) of Willow, bearsome of these modes of inflorescence determine the nature of the fruit.

Catkin (Amentum) of Willow, bearing male flowers, each of which arises from a scale (Squama), or, or, other words, a scaly bract. There are numerous flowers and bracts in the catkin.

In the Spike, the Spadix, and the Catkin, the floral axis is elongated. Other cases occur in which sessile flowers are produced on a shortened axis. The Head (Capitulum) is a congeries of sessile flowers, supported on a more or less flattened axis (receptacle), and expanding centripetally. In the American Button-bush the heads are globular, in some species of Teazel elliptical, while in Scabious, and in Composite plants, as Sunflower, Dandelion, Thistle, Burdock, and Marigold (Fig. 151), they are somewhat hemispherical, with a flattened, slightly hollowed, or convex disk. In the latter class of plants, besides the general bracteal envelope, called the involucre, there are frequently chaffy and setose bracts at the base of each flower. In Dorstenia (Fig. 156) the receptacle of the flowers varies from a flattened disk to one in which the edges are incurved and turned upwards. When this incurvation of the receptacle is complete, so as to form a hollow cavity bearing the flowers inside, the inflorescence is like that of the Fig (Fig. 157). By this mode of formation the flowers at the circumference are turned towards the apex, while the real centre remains next to the stem of the plant.

Determinate or Definite Inflorescence.—In this inflorescence, the flowers, in place of arising from axillary buds, are considered as represented by terminal buds, beyond which the axis does not extend. The simplest form is that in which a single floral axis is produced, terminated by a solitary flower, as in Gentianella (Fig. 159), with two opposite leaves, c, at the base of the inflorescence. When such an inflorescence branches, it is by the production of axillary buds, whence arise floral axes, terminated, as the first axis, by solitary flowers. The axes are thus arrested in their development, and do not grow in an indeterminate manner. This kind of inflorescence is very commonly associated with opposite leaves, but it occurs also in plants with alternate leaves, as Lint.*

If such a plant as Gentianella, with opposite leaves, produces additional flowers, it does so in a descending series, that is to say, the buds produced by each of the opposite leaves on the stem (Fig. 159, c), and bearing solitary flowers, expand after the flower terminating the primary axis, and successively later as we proceed downwards. Thus, the expansion of the flowers is centrifugal, i.e., farther and farther from the central terminal bud of the primary axis, and later as regards time. A racemose or spiked inflorescence of this kind would be at once distinguished by the upper flowers being first expanded, and not the lower, as in the indefinite

*Pl. CXV. fig. 2.

Botany. raceme and spike. The order in which the flowers expand determines the nature of the inflorescence. Attention must be paid to the axis terminating in a single flower, to the bract which it gives off laterally, and to the flower-bud produced between the bract and the axis.

When the different floral axes in the definite inflorescence come off close to each other, and are much shortened, there is often apparent confusion in the arrangement, and it is only by noticing the development of the flowers in the different clusters that we can pronounce on the nature of the inflorescence. The branched kind of definite inflorescence is seen in the *Cyme*. This is a corymbose inflorescence, more or less branched, forming a cluster of flowers, which is either flattened at the top, or has a rounded contour. It is illustrated in the Elder, the Hydrangea, and the Laurustinus. It appears like a combination of the umbel and corymb, but is known by its centrifugal floral expansion.

The mode in which the cyme is formed may be studied in the common Spearwort, and other species of Chickweed. In them, as shown in Figure 168, there is a solitary flower, a, which terminates the primary axis, and has two opposite leaves, b, at its base. Each of these leaves (bracts) gives origin to flower-buds, which form axes, c c, ending in solitary flowers. Each of these secondary axes in their turn bear opposite bracts, or leaflets capable in the same way of forming tertiary axes, with solitary flowers, and so on until the plant is exhausted, or the axes produced have no leafnodes. This division, by pairs of axes, forms a spreading, loose, dichotomous (dividing by pairs, δίχα, in two ways, and τομή, a section) cyme. If three whorled leaves develop axes, the cyme becomes trichotomous (dividing by threes). Sometimes the two bracts on the axis do not produce flower-buds, and then the primary axis, with its single flower, is alone present, with two empty bracts on the stalk, as seen in the Heart's-ease (Fig. 169, b) which produces a unifloral cyme.

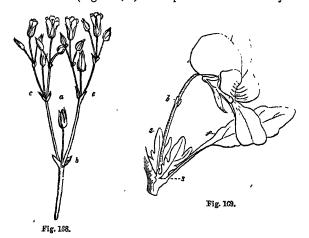

Fig. 168. Dichotomous cyme of Mouse-ear Chickweed (Cerastium). The primary floral axis ends in a solitary flower, a, which expands first. The axis bears two bracts, b, each of which gives origin to secondary axes, each ending in a solitary flower, and bearing two bracts, c, which in their turn give rise to unifioral tertiary bract-bearing axes, and so on. When there bracts are produced, and three axes, the cyme becomes Trichotomons. When the axes are much shortened, and the flowers are brought nearer to each other, the formation of the cyme is rendered obscure.

169. Unifioral cyme of the Pansy (Viola tricolor). The primary axis bears a single flower, and below it are two bracts, b, indicating the points where secondary axes would appear if present. The bracts are empty. The leaf is marked f, s s, stipules.

At other times the primary axis produces a solitary flower, and only one of the bracts developes a flower-bud, as in the common Bind-weed, in which we meet with bifloral cymes, and also unifloral cymes.

If the flower-buds on one side of a dichotomous cyme are the only ones developed, it becomes unilateral, and often turns round in a peculiar way, so as to resemble a snail, or the tail of a scorpion, and hence it is denominated helicoid

or scorpioid. The terms gyrate and circinate are also some- Potany. times applied. The same thing occurs also in alternateleaved plants, where each leaf or bract produces one flower, and a flower-bud which elongates into an axis between the first flower and the bract. In such cases the flowers seem to be placed opposite the leaves, and when the leaves dis-

appear, or are abortive, as in many of the Borage tribe, it is difficult to determine whether the inflorescence is a one-sided (unilateral) raceme, or a series of single-flowered axes, produced in a racemose manner. The appearance of the helicoid cyme is represented in Figure 170, in the case of the Forget-me-not; on the axis a leaf, c, gives origin to a flower-stalk, ending in a solitary flower, a; there are no bracts developed on this primary floral axis, but two racemose cymes, b b, are given off, each of which curls up in a circinate manner. These cymes are formed by a series of single-flowered axes, which are produced in a secund manner, i.e., only on one side. The

ner, i.e., only on one side. The theoretical formation of this inflorescence is given in Figure 171, where the primary floral axis, 1, ends in a solitary flower, and so do the other axes from 2 to 10. The small dotted lines indicate the points where floral leaves (bracts) occur. The expansion of the

flowers is centrifugal. The flower of axis 1 expands first;

Fig. 170.

this axis gives origin to a flower-bud forming axis 2; in its turn axis 2 expands its solitary flower, and gives rise to axis 3, and so on. Thus, the inflorescence is composed of a series of unifloral axes produced from each other, and not alternating to right and left, but always developed on one side, forming a broken line, which has a tendency to return upon itself. In the diagram ten unifloral axes are shown, each bearing a solitary flower. When the bracts are abortive, as in the

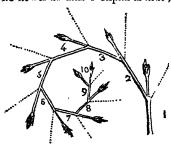

Fig. 171.

Fig. 171.

Diagram to illustrate the formation of a scorpioid cyme. The first axis, 1, ends in a solitary flower. On one side of this axis a node is produced, which gives rise to the secondary axis, 2, bearing a solitary flower, which is developed after 1. This axis in its turn produces a floral node, giving rise to a tertiary underal axis, 3, and 30 on, up to 10. At the same time the inflorescence becomes curved, as the development of the axes takes place on one side. The non-developed nodes are marked by dotted lines opposite the points whence the floral axes arise.

Borage tribe, the nature of the inflorescence is not detected at first sight. The formation of the different axes between the previously expanded flower and the bract, indicates the nature of the inflorescence. When the internodes of such a floral axis are shortened, and the bracts disappear, some anomalous inflorescences are produced, as in Solanaceæ.* The appearance of a peduncle opposite a leaf leads often to a correct conclusion in regard to the morphology of the inflorescence; in the same way as has been already noticed in the case of the tendrils of the Vine, which are leaf-buds producing separate axes, in a centrifugal manner.

*Plate

Botany.

In some kinds of cymose inflorescence the flowers are sessile on an elongated axis, forming a cymose spike; in other instances they are nearly sessile, and form a rounded head or short spike, called a Glomerulus, as seen in species

of nettle, and in the Box. Sometimes stalked flowers arise from the same part of the axis, in the form of a cluster, called a Fascicle, as a *Pl. CXIV. in the Mallow* (Fig. 172), and in species of Pink. In the case of Labiate plants, as Mint, and Deadnettle (Fig. 173), the flowers appear to be in whorls, but n reality they arise

in two clusters or fascicles, called Verticillasters, which are cymes bearing a few nearly sessile

flowers, expanding centrifugally. Each cluster is produced from one of the opposite leaves. What are properly called whorled flowers are seen in the Common Mare's-tail (Hippuris vulgaris), in which each leaf of the whorl produces a single flower.

Mixed Inflorescence.—There are certain kinds of inflorescence in which there is a combination of the definite and indefinite forms. These have been called Mixed. They are by no means uncommon in the Vegetable Kingdom, and they require to be studied carefully. In Composite plants, the branches bearing the heads of flowers (capitula) are often developed centrifugally, while in the individual heads the expansion is centripetal. The general inflorescence, in such a case, may be said to be definite, while the partial inflorescence is in-

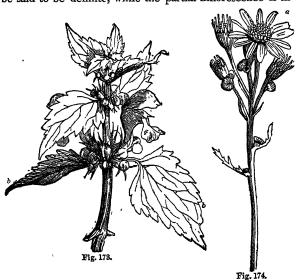

Fig. 173. Flowering stalk of the White Dead-nettle (Lamium album). The bracts, b, are like the ordinary leaves of the plant, and produce clusters of flowers in their axil. The clusters are called Verticallasters, and consist of flowers which are produced in a centrifugal manner, the central one expanding first. Hence the inflorescence is definite. The flowering stalk continues, however, to elongate in an indefinite manner.

is definite. The nowering stalk continues, now ever, to enoughe in an indefinite manner.

174. Flowering stalk of a kind of Groundsel (Senecio). The flowers are in heads (capitula), and open from the circumference inwards in an indefinite centripetal manner. The heads of flowers, on the other hand, taken collectively, expand centrif ugally—the central one, a, first. Each head of flowers terminates a separate axis. They form together a definite corymb. The inflorescence is called mixed.

definite. Thus, in Figure 174, the central head a, of flowers

is expanded, while the others are only partially so; the in- Botany. florescence is mixed, and the whole puts on the aspect of a corymbose cyme, with the flowers in each head centripetal. In Labiate plants (Fig. 173) the general inflorescence is centripetal, while the verticillasters are centrifugal.

The Flower and its Different Parts.

a. Symmetry and Morphology of the Flower.

The term Flower, in botanical language, is not confined to the mere showy parts in which the gay and brilliant hues reside, but embraces all the organs, however inconspicuous, which are concerned in the production of seed. These organs, or parts of the flower, must all be considered as modifications, or, as it may be more properly expressed, analogues of leaves. In their structure and arrangement they are similar to the foliar organs, and they follow the same laws

When a student, of development. therefore, has acquired a knowledge of the anatomy and arrangement of leaves, he is prepared to enter upon the consideration of the floral organs.

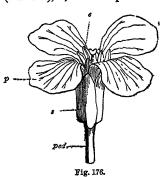

When the flower is complete it consists of four whorls (verticils), placed alternately within each other. The two alternately within each other. internal are the Stamens and Pistils, which are the essential organs of reproduction, and the two external are the Calyx and Corolla, constituting the floral envelopes, or protective coverings. In Figure 175, an ideal section of a complete flower is given, each whorl consisting of five parts, which are arranged alternately. In Figures 176 and 177 the

parts of the flower are represented; the calycine whorl (calyx), s, the corolline whorl (corolla), p, the staminal whorl (stamens), e, and the pistilline whorl (pistil), sti, being all

Fig. 175.

Diagram of a completely symmetrical flower, consisting of four whorls, each consisting of free parts. The outer row is the cally formed of five peats, the second is the corolla of five petals, alternating with the sepals; the third is the andrecolum, consisting of five stamens, alternating with the petals; the central whorl is the gynocium, consisting of five carpels, alternating with the petals; the central whorl is the gynocium, consisting of five carpels, alternating with the stamens. Fig. 175.

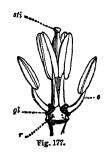

Fig. 176. Flower of Wallflower (Cheiranthus Cheiri). The stalk of the flower is called the pedunole, ped; the calyx, s, consists of four sepals; the corolla, p, is formed of four petals, arranged crosswise; the stamens, e, constitute the androecium or staminal whorl, and in the centre is the pistil.

17. The Essential organs of reproduction of Wallflower. The stamens, e, are tetradynamous, i.e. four long and two short, with glands, gl, at their base, and are inserted into the receptacle or torus, r; the pistil is in the centre, and the summit of it, or the stigma, is marked sti.

inserted into a common receptacle, r, which may be considered as the termination of the peduncle, ped, or flow. -

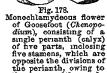

The Calyx is the outer covering (Fig. 176, s), formed of whorled leaves, called Sepals, which are generally of a greenish colour. The Corolla is the next covering, composed of whorled leaves, called Petals (Fig. 176, p), often showy, arranged alternately with the sepals. The calyx and the corolla are sometimes included under the common name of Perianth or Perigone ($\pi \epsilon \rho \iota$, around, $\ddot{a} \nu \theta o s$, flower, and youn, offspring), especially in cases where both are similar in appearance, as in the Tulip. A flower with a

Botany. single perianth (Fig. 178) has a calyx only, while one with a double perianth may be considered as having both calyx

and corolla. Some restrict the term perianth to cases where the envelope surrounds a staminiferous flower, while perigone is applied to the envelope of a flower having both stamens and pistil,

or a pistil only.

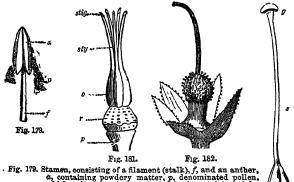

The Stamens (Fig. 177, e) are placed within the petals, with which they alternate. Each stamen consists of a peternate. Each stamen consists of a peculiar folded leaf, called the Anther Fig. 179, a), either sessile (unstalked), or supported on a stalk, denominated a Filament (Fig. 179, f), and containing powdery matter called Pollen (Fig. 179, p), which is discharged through ing powdery matter called Pollen (Fig. 179, p), which is discharged through

slits or holes. The whole staminal whorl, taken collectively, is styled the Andrœcium (ἀνηρ, male, and ὀικίον, habitation).

The Pistil is the central organ (Fig. 180), below and around which the other floral whorls are arranged. It consists of one or more folded leaves, called Carpels (καρπὸς fruit), either separate (Fig. 181), or combined (Fig. 180), and collectively forming the pistilline whorl, which is denominated the Gyncecium (γυνή, female, and οικίον, habitation). The parts distinguished in the pistil are the Ovary (Fig. 180, o), which is the lower portion inclosing the Ovules destined to become seeds, the Stigma (Fig. 180, g), a portion of the loose cellular tissue, uncovered by epidermis, which is either sessile on the apex of the ovary, as in the Poppy, or is separated from it by a prolonged portion called the Style (Fig. 180, s). The essential organs must be present, in order that seed may be produced, but the floral envelopes may be wanting, and still the reproductive functions may be performed. When both calyx and corolla are present, the flower is Dichlamydeous (δìs, twice, χλαμὺς, a covering), when the corolla is wanting, the flower is Monochlamydeous (µovos, one), and when both are wanting, it is Achlamydeous (a, privative).

All the organs of the flower are attached to the extremity of the flower-stalk, and the part on which they are situated has received the names of Thalamus, Torus, and Receptacle (Figs. 177, 180 r). The different organs are verticillate leaves, produced at nodes which are placed close to each other, without the intervention of marked internodes. Each organ forms one or more whorls, and the parts of each whorl are

. Fig. 179. Stamen, consisting of a filament (stalk), f, and an anther, a, containing powdery matter, p, denominated pollen, which is discharged through slits in the two lobes of the

which is discharged through shift in the Not Note of the overy, o, containing ovules, the style, s, and the capitate stigms, g. The pistil is placed on the receptacle, r, at the extremity of the peduncle.

181. The graceium (pistil) of Columbine (Aquilegia uniqueris), situated on the receptacle, r, which occupies the summit of the peduncle, p. The pistil consists of five carpels, each of which has an ovary, o, containing ovules, a style, Fig. 180. sty, and a stigms, stig.

182. Calva and pistil of Fraxinella (Dictamnus Frazinella). The pistil consists of several carpels, which are elevated on a stalk prolonged from the receptacle. The stalk is called Gynophore or Thecaphore.

placed alternately in relation to those of the whorls next it.

In certain instances the internodes are lengthened, and thus Botany. the different whorls are separated from each other, just as in verticillate leaves. Thus, in some plants of the Caper tribe, there is an enlarged, rounded, disk-like receptacle (anthophore, and popen, to bear), bearing the petals, from the centre of which arises a stalk or internode (androphore, aup, stamen), bearing the stamens, and finally, another lengthened internode (gynophore, ywn, pistil) bearing the pistil. In some cases the pistil is stipitate, or supported on a stalk which proceeds from the centre of the receptacle. This is seen in the Caper-plant, in the Passion-flower, in some of the Chickweed order, and in Fraxinella (Fig. 182).

In the Geranium, the part of the receptacle bearing the pistil is prolonged in the form of a long beak-like (rostrate) process, to which the styles are attached (Fig. 183, a). In

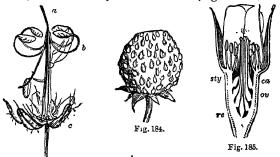

Fig. 183.

Fig. 183. The calvx and beak-like process of Geranium, with the parts of the pastl (the carpels) curled upwards, so as to scatter the seed; a, the extremity of the restrum or beak, whence the name crane's bill is derived); b, the carpels curled up by means of the styles which are attached to the beak; c, the calvx.

184. Fruit of the Strawberry (Fragaria vesca), consisting of an enlarged succulent prolongation of the receptacle, bearing on its surface numerous carpels, which are often erroneously called seeds. The calvx is seen at the lower part.

185. The fruit of the Rose cut vertically. The receptacle, rc, lines the interior of the calvx, ca, and the carpels with their ovaries, oz, and the styles, sty, are attached to it. The stamens and petals are seen at the upper part, attached to the calvx.

the Strawberry (Fig. 184) the receptacle, after giving origin to the calyx, corolla, and stamens, becomes enlarged and succulent, bearing the parts of the pistil on its surface, and constituting what is commonly called the fruit. The sacred Bean of India and of the Nile (Nelumbium), has a large topshaped (turbinate) receptacle inclosing the pistils. In the fruit of the Rose the portion of the receptacle (Fig. 185, re), bearing the parts of the pistilline whorl, ov, is adherent to the inner surface of the calyx, ca. In some monstrous specimens of Avens and Rose there is occasionally an unusual development of the central part of the receptacle, so that the pistilline leaves become arranged alternately on an axis which ends in an abortive flower-bud.

The leaves and the different parts of the flower are considered by botanists as homologous (δμόλογος, having an agreement). In other words, they are constructed on the same plan, and the forms which they assume depend on the nature of the functions which they are required to perform. Leaves being concerned in nutrition and in the assimilation of food, assume an arrangement and colour fitted for these purposes, and have all their parts developed in conformity with the functions allotted to them. The parts of the flower, on the other hand, are concerned in the function of reproduction, and in their structure and development are fitted for the office which they have to perform. The parts of the flower originate in the same way as the leaves, in the form of simple cellular projections from the axis. The appearances which they afterwards present depend on organogenic (organ-producing) laws of development—the arrangement of the cells and vessels, and their contents, being modified in each special organ.

The leaf is considered as the Type of all. This idea was started by Linnæus, and was afterwards more fully brought forward by Goethe. In speaking of the parts of the flower

Botany. as metamorphosed or modified leaves, it must not be supposed that we mean that these parts have, at any period of their existence, been true leaves. All that is implied in the statement is, that both are formed on the same general plan, that both are arranged upon the same principle, and that one law pervades their morphology. The cell from which the leaf is formed is no doubt very different as regards the organogenic law impressed upon it from the cell which gives rise to a sepal, a petal, a stamen, or a carpel. Nevertheless, when we examine the parts scientifically, we perceive certain homologies in form and structure belonging to the one set of organs which are represented in the other. This morphological view of the organs of the flower associates them with the leaves in a very interesting manner, and enables us to give a philosophical exposition of the harmonies subsisting between them.

In passing from leaves to flowers, there are certain intermediate organs called bracts, which are merely altered or modified leaves, producing flower-buds at the part where they emerge from the stem. From these we proceed to the flower-stalks, which are branches bearing flower-buds in place of leaf-buds. The outer whorl of the flower has generally more or less of the appearance and colour of leaves, and, in many instances, the leaflets produced on the flower-stalk pass by insensible gradations into sepals. Between sepals and petals there are transition forms, as seen in the White Water-Lily, the Magnolia, and many plants where the colour of both is similar. The petals, in their turn, sometimes become narrowed and altered, so as to pass into stamens, as in the White Water-Lily, where it is scarcely possible to say where the different whorls end. It is very rare to find the stamens passing into the pistil. In the case of monstrosities, however, produced by cultivation, the pistil undergoes such changes as to prove that it is formed on the same type as the rest. Occasionally all the parts of a flower, as in some monstrous specimens of Dutch Clover, are converted into leaves.

When sepals are changed into petals, petals into stamens, or the latter into carpels, the alterations are said to be in the ascending series, and it is called a case of ascending or progressive metamorphosis. By cultivation, and other causes, this series of phenomena is sometimes reversed. Thus, in the double cherry, the pistil is frequently altered, so as to appear in the form of one or more leaves (Fig. 186, a and b); and in double flowers the stamens are changed more or less completely into petals. In Figure 187 is exhibited

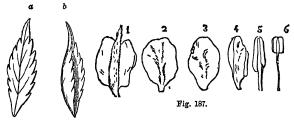

Fig. 186.

Fig. 186. The carpel of the double-flowering Cherry. In this plant the fruit is abortive, and in its place one or more leaves are produced. The carpellary leaf is either expanded, a, or folded, b. This shows that the fruit of the Cherry is formed on the same type as the leaf.
... 187. Transformations in the stamen of the Rose. The complete stamen, b, is altered gradually, passing through the states represented at 5, 4, and 3, until it becomes a complete petal, 2, and the petal at 1 begins to assume the appearance of a sepal, with a strongly-marked midrib prolonged beyond the apex.

the series of changes through which a stamen of the Rose passes, from the normal state, 6, until the complete petal, 2, is formed, and this, in its turn, becomes altered, as seen in 1, so as to resemble a coloured sepal, with a prominent and projecting midrib. In some cultivated flowers the petals assume a green colour, so as to resemble the calyx, which, in its turn, often appears like true leaves. This is called retrograde metamorphosis. In certain cases the

floral axis, in place of bearing flowers, produces whorls of Botany. leaves. The alteration in such instances is either complete, or there is a partial change of the organs, some of them remaining unaltered. It sometimes happens that, from the centre of the flower, a leaf-bearing axis is prolonged at the expense of the pistil. All these cases prove the general law of development in leaves and flowers to be in reality the same, and they point out the means of explaining many of the anomalous appearances presented by the flower.

The parts of the flower being thus considered as modified leaves, we naturally look for a similar mode of arrangement. As leaves are alternate, opposite, and verticillate, we may expect the parts of the flower to be arranged in the same manner. We might conceive a flower, as in the ideal representation in Figure 188, to be formed of a sepal, c, a petal, p, a stamen, s, and a pistil, f; each of the parts alternating with that next to it, and separated by an internode, and all arising from a single bract, b. In plants such as Hippuris, with one stamen, and one pistil, and an abortive calyx, such may be reckoned the tendency, although, from non-development of certain parts, the flower becomes incomplete. We generally find that the parts of the flower are arranged in twos, threes, fours, or fives.

When the parts of a flower appear in pairs, they may be considered as formed of opposite decussate leaves. In Figure 189, there is an ideal representation of such a flower, with its bracts, b, its sepals, c, petals, p, stamens, s, and carpels, f, separated by marked internodes. If the internodes in Figures 188 and 189 were taken away, or very much shortened, we would then have the arrangement usually seen in the flower. These diagrams also illustrate what occurs in the case of some plants, where the different floral whorls are distant from each other. When the parts of a flower are arranged in threes, fours, or fives, they may, if placed in a circle at the same level, be regarded as verticils, or, if at different levels, as following a spiral arrangement.

A flower is said to be Symmetrical when each of its whorls consist of an equal number of parts, or when the parts of any one whorl are multiples of that preceding it. Thus, a symmetrical flower may have five sepals, five petals, five stamens, and five carpels, or the number of any of these parts may be ten, twenty, or some multiple of five. In Figure 175 there is a diagram of a symmetrical flower, with five parts in each whorl, alternating with each other. In

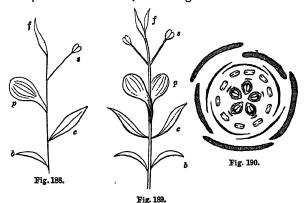

Fig. 189.

Fig. 189. An ideal representation of a flower arising from a bract, b, and formed by a single sepal, c, a single petal, p, a single stamen, s, and a single carpel, f; the parts being alternate, and separated by internodes.

189. An ideal representation of a dimerous flower, formed of two parts in each whorl. The bracts, b, the sepals, c, petals, p, stamens, s, and carpels, f. The parts of the flower are decussate, and thus follows a law of alternation. Each whorl is separated by an internode. If the internodes were removed the whorls would be closely applied to each other, as in ordinary flowers.

190. Diagramatic section of a symmetrical pentamerous flower of Stone-ore (Scdam), consisting of five sepals externally, five petals alternating with the sepals, ten stamens in two rows, and five carpels containing seeds. The dark lines on the outside of the carpels are glands.

Figure 190 there is a section of a symmetrical flower of

Botany.

Stone-crop, with five sepals, five alternating petals, ten stamens in two rows, and five carpels. Figure 191 shows a flower of Heath, with four divisions of the calyx and corolla, eight stamens in two rows, and four divisions of the pistil. In Figure 192 there are three divisions of the calyx, corolla, and pistil, and six stamens in two rows. In all these cases the flower is symmetrical. Flowers in which the number of parts in each whorl is the same are Isomerous (isos, equal, and $\mu \acute{e} \rho os$, a part); when the number in some of the whorls is different, the flower is Anisomerous (auros, unequal). When the parts of any whorl are not equal to, or some multiple of the others, then the flower is Unsymmetrical. This is seen in Veronica as given in Figure 193, where there are four divisions of the calvx, four of the corolla, and only two stamens, and two parts of the pistil.

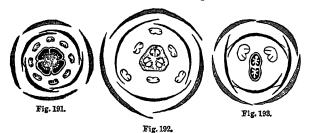

Fig. 191. Diagram of the flower of Heath (Erica), having four sepals, four divisions of the corolla, eight stamens in two rows, and four divisions of the pistal. The flower is tetramerous, complete, symmetrical and recorder.

sions of the pisth. The lower is tetramerous, complete, symmetrical, and regular.

192. Diagram of the symmetrical trimerous flower of Fritillary, having three divisions of the two outer whorls, and of the pisth in the centre, and six stamens in two rows.

193. Unsymmetrical flower of Speedwell (Veronica). The two outer whorls consist of four parts each, while the two inner have only two parts.

Symmetry, then, in botanical language, has reference to a certain definite numerical relation of parts. A flower in which the parts are arranged in twos is called *Dimerous* ($\delta \iota s$, twice, and $\mu \acute{e} \rho os$, a part), the symmetry being Binary, and the arrangement marked thus $\sqrt[4]{\cdot}$. When the parts of the floral whorls are three, the flower is Trimerous ($\tau \rho is$, thrice), and the symmetry being Ternary or Trigonal, is marked ... When the floral pieces are in a series of four, the flower is Tetramerous (τέτρα, four times), its symmetry being Quaternary, and marked . A Pentamerous (πεντε, five) flower, marked \$\sqrt{\psi}\$, has Quinary or Pentagonal symmetry. The symmetry which is most commonly met with in the vegetable kingdom is trimerous and pentamerous—the former occurring generally among Monocotyledons, the latter among Dicotyledons. Tetramerous symmetry occurs also among Dicotyledonous plants, and the numbers 2 and 4 prevail in the reproductive organs of Acotyledons.

The parts of the flower are, generally speaking, arranged so that those of one whorl are alternate with those of the next whorl. Thus, the petals alternate with the sepals, and the stamens with the petals. When the numbers in any series, such as the stamens, are multiplied, and the flower is still symmetrical, then the organ is found to consist of a definite number of whorls alternating with each other. Thus, in diagram 192, the stamens are six in place of three, and they are arranged in two alternating whorls—the parts of the outer whorl alternating with the petals, and with those of the inner series. The pistilline whorl is more liable to changes than the other parts of the flower. It frequently happens, that when it is fully formed, the number of its parts is not in conformity with that of the other whorls. In such circumstances, however, a flower is still called symmetrical, provided the parts of the other whorls are normal.

The various parts of the flower have a certain definite relation to the axis. The terms superior and inferior have reference to their position. Thus, in axillary tetramerous flowers (Fig. 191) one sepal is next the axis, and is called superior or posterior; another next the bract, is inferior or

anterior, and the other two are lateral; the petals (when Botany. present) being alternate with the sepals, are so placed, that

Fig. 194.

Fig. 194. Diagram of flower of Rose, showing one division of the calyx superior or next the axis, and two inferior or next the bract. The petals are arranged alternately with the calycine segments, and hence two of them are superior, and one inferior.

... 195. Diagram of flower of Sweet-pea (Lathyrus), showing five parts of the calyx of which two are superior, one inferior, and two lateral; five parts of the corolla, of which one is superior, two inferior, and two lateral; en stamens in two rows; one carpel, in consequence of four being undeveloped.

two are posterior, and two anterior; while the four stamens are arranged like the sepals. In a pentamerous flower it happens, that either one sepal is superior, two inferior, and two lateral, as in the calyx of Rosaceæ (Fig. 194); or two are superior, one inferior, and two lateral, as in the calyx of Leguminosæ (Fig. 195). The reverse, of course, by the law of alternation, is the case with the petals.

A flower normally consists of four whorls, calyx, corolla, stamens, and pistil, and when these are all present, the flower is *complete*. When each whorl consists of the same number of parts, or of a multiple of the parts, successively alternating with one another, we have seen that the flower is symmetrical. When the different parts of each whorl are alike in size and shape, the flower is regular. The absence of any of the whorls renders the flower incomplete. Want of correspondence in the number of the parts of the whorls causes want of symmetry, as has been already shown, while differences in the size and shape of the parts of a whorl makes the flower irregular, as in the papilionaceous flower represented in Figure 195.

In their earliest stage of development all the parts of the floral whorls are regular and symmetrical, consisting of similar minute cellular papillæ arising from the axis. The alterations in their regularity and symmetry depend on changes taking place during their growth. These alterations are traced to the adhesion of one part to another, the union of different whorls, irregular growth, complete suppression of one or more parts or whorls, degeneration or degradation, multiplication of parts, and chorisis or deduplication.

A flower becomes incomplete by the non-development, or by the transformation of one or more whorls. It becomes irregular by one or more parts of a whorl being enlarged or diminished in size, and by irregular cohesions; and it becomes unsymmetrical when some of the parts of one or more whorls are suppressed, so that their numerical relations do not correspond. The consideration of all the changes which the parts of plants undergo, or, in other words, the permanent deviations from what may be considered as their normal state, is included under the term Teratology (τέρας, a monster, and λόγος, discourse). Every alteration in the organs of the flower may be traced to the morphological laws to which we have already alluded. In treating of the separate floral whorls, notice will be taken of the changes which they undergo; in the meantime some general remarks will be made on the causes to which these changes are referred.

Union or adhesion of the floral whorls, or of the parts composing them, gives rise to various changes in form and symmetry. The adhesion is sometimes very irregular, so that certain parts are more completely united than others. Many forms of irregular flowers are due to this cause. The non-

#Plate

fig. 2.

Botany. development of whorls gives incompleteness to the flower. The absence of the corolline whorl renders a flower Apetalous or Monochlamydeous, the absence of both the calycine and corolline whorl makes the flower Naked or Achlamydeous. The suppression of the stamens, or of the pistil, renders the flowers *Unisexual*. The non-appearance of a whorl deranges the relation of the different parts, and destroys their alternation. Thus, in the apetalous flower of the Nettle, the stamens, in place of being alternate with the whorl on their outside, are opposite to it, and this relation of parts leads to the detection of the suppressed whorl.

Various parts of the flower are apt to become abnormal, or degenerate by Transformations of different kinds. Some of the parts may be converted into scales or into hairs. The floral leaves of the catkin of the Willow, and those of the Hop, are membranous scales, while those of the Cone are hard scales; the Wig-tree (Fig. 158) produces hairs instead of flowers on some of its peduncles, and the calvx of the Dandelion,* and other compound flowers, assumes the form of hairs, which remain attached to the fruit. In double flowers the stamens and pistils degenerate by being converted into

Sometimes the parts of a flower are increased in number by the growth of additional parts, or by the splitting of organs during their development. This latter process is called Chorisis (χώρισις, separation), and seems to account satisfactorily for the appearance of certain anomalous parts which do not follow the law of alternation. This chorisis consists in the formation of two parts out of one, the separated parts being either placed one in front of the other by transverse chorisis, or side by side by collateral chorisis. The lamina of a petal may be split in such a way that a scale is produced on part of it, as seen in Lychnis. Stamens may be divided so that two standing collaterally are produced in place of one; in this way some account for the abnormal state of the stamens in cruciferous flowers, such as Stock and Wallflower. In these plants, while the calyx and corolla consist of four parts, the stamens are six (Fig. 177), owing, it is said, to collateral chorisis of two of them. The flowers are thus considered normally tetramerous. In the Fumitory there are two sepals, four petals in two rows, and six stamens. The latter consist of two perfect stamens, and four incomplete, which are considered as being produced by collateral chorisis of two stamens. In this way the flower would be normally dimerous. When the parts of contiguous floral whorls are opposite to each other, in place of being alternate, the occurrence may be accounted for, either by suppression of a whorl, or by chorisis.

b. The Flower-Bud.

The various parts of the flower, consisting of the floral envelopes and the essential organs of reproduction, are contained in the flower-bud. They appear at first in the form of small cellular mammillæ, or prominences, the parts of each verticil being equal and separate. In their development (organogeny) they follow the same order as leavesthe extremities of each of the parts being first formed, and irregularities, caused by adhesion and other causes, occurring only during the progress of growth. In general the whorls are developed successively, from the calyx to the pistil; but, in some instances, the petals are retarded in their growth, so that the stamens are completed before them.

The terms Prafloration (pra, before, and flos, flower) and Æstivation (æstivus, pertaining to summer) are used to express the arrangement of the different parts of the flower in the flower-bud. The relation of these parts to each other is similar to that which occurs in the leaf-bud, and which has been considered under præfoliation. The same terms are also used to express the nature of many of these arrangements. As regards each leaf of the flower, it

is either spread out, as the sepals in the bud of the Lime- Botany. tree; or folded upon itself (conduplicate), as in the petals of some species of Lysimachia; or slightly folded inwards or outwards at the edges, as in the calvx of some species of Clematis, and of some herbaceous plants; or rolled up at the edges (involute or revolute); or corrugated and crumpled,
PI. CXII. as the petals of the Poppy.

The position of the parts of the flower relative to each other, in the bud, gives origin to the terms valvular, contortive or twisted, and imbricated. In the first two the parts are placed at the same level, in a circular manner, while in the latter they are at different heights, and follow a distinctly spiral order. æstivation is Valvular, or the parts are arranged in a valvate manner (Fig. 196), Diagram to illustrate valvate when they are so applied as to be in sestivation, in which contact at their edges without any folding. They are in a circular verticil. When

Fig. 196.

the parts of the verticil are slightly folded inwards at their edges the æstivation is Induplicative (Fig. 197), when folded

Fig. 198.

Fig. 197. Diagram to illustrate induplicative or induplicate estivation, in which the parts of the verticil are slightly turned inwards at the

which the parts of the verticil are singlify turned inwards at the edges.

198. Diagram to illustrate reduplicative or reduplicate astivation, in which the parts of the whorl are slightly turned outwards at the edges.

199. Diagram to illustrate contortive or twisted astivation, in which the parts of the whorl are overlapped by each other in turn, and are twisted on their axis.

outwards Reduplicative (Fig. 198). When the parts of the

corolla are united they are occasionally folded in a plaited

In Contortive æstivation the parts are in a circle, or apparently so, and one edge of each is directed inwards, so as to be overlapped by the contiguous part, while the other edge covers the margin of the part adjacent on the other side; each part also is, as it were, twisted on its axis, and the whole whorl exhibits a convolute appearance (Fig. 199). It is well seen in the unexpanded petals of Malvaceous plants,* in the corolla of Cyclamen, and in that of many Apo-*Pl. CXIV. cynaceæ, which were called Contortæ by old authors.

The æstivation called Imbricated or Imbricative embraces those bud arrangements in which the parts are placed at different heights so as to overlie each other, and form a more or less evident spiral cycle (Fig. 200). When the parts of a floral whorl are five, as is the case in many Exogens, it is often found that there are two parts wholly on the outside, two completely internal, and one intermediate, overlapped at one edge by one of the outer parts, whilst its other edge covers one of the inner parts (Fig. 201). This is Quincuncial or Spiral imbrication, and is the normal arrangement in pentamerous flowers, corresponding with the arrangement in leaves. In personate flowers, as Frogsmouth, a variety of imbricated æstivation occurs, called Cochlear, in which the second part of the cycle, in place of being external (as in the ordinary quincuncial arrangement), becomes wholly internal. When imbricated æstivation occurs in trimerous flowers, there is one part outside, one inside, and one intermediate, the arrangement being 1, as in When the flower is tetramerous, there are two outer parts and two inner parts; this being analogous to what occurs in opposite decussating leaves. In pea-like

Botany. blossoms it is usual to find a modification of imbricated

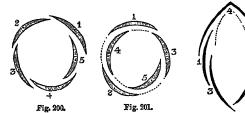

Fig. 202.

Fig. 200. Diagram to illustrate imbricative or imbricated estivation, in which the parts are arranged in a spiral cycle, following the order indicated by the figures 1, 2, 3, 4, 5.

201. Diagram to illustrate the quincuncial estivation, in which the parts of the flower are arranged in a spiral cycle, so that 1 and 2 are wholly external, 4 and 5 are internal, and 3 is partly external and partly overlapped by 1.

202. Diagram of a papilionaceous flower, showing vexillary estivation, 1 and 2 the alse or wings, 3 a part of the carina or keel, 4 the vexillum or standard, which, in place of being internal, as marked by the dotted line, becomes external, 5 the remaining part of the keel.

The order of the cycle is indicated by the figures.

æstivation, called Vexillary, in which the large petal called the vexillum, and which is superior or next the axis, overlaps the rest (Fig. 202). In some instances, as in the Judastree, the vexillum is included between the lateral petals (alæ), as represented by the dotted lines, 4, Figure 202. The different verticils of the flower have not always the same æstivation. In the Mallow tribe the calyx is valvate, while the corolla is twisted; in St John's Wort the calyx is imbricated and the corolla twisted; in the Rock-rose the three inner sepals are twisted in one direction, while the petals are twisted in an opposite direction.

c. The Floral Envelopes. * The Calyx or Outer Floral Envelope.

The Calyx is the outer floral envelope, and is composed of a whorl of leaves called Sepals. These leaves have usually the structure and appearance of ordinary leaves, as regards the distribution of their cells and vessels. They are frequently of a greenish hue, having chlorophyll in their cells, and stomata on their lower (outer) epidermal covering. When not green the calyx is said to be coloured, as in Columbine, Monkshood, Larkspur, Fuchsia, and Indian cress. It is not common to find the individual sepals divided. Sepals are usually sessile leaves, having no stalks. They are either distinct from each other, as in Wallflower, or they are combined, as in the Melon. When the sepals are of the same size and form, the calyx is regular, when not so it is irregular.

When the sepals are separate the calvx is Polysepalous. Polyphyllous, or Dialysepalous (πολύς, many, διαλύειν, to separate), the number of sepals being marked by the Greek numerals prefixed. Thus, disepalous means a calyx with two distinct sepals; trisepalous with three; tetrasepalous with four; pentasepalous with five; hexasepalous with six: or the Greek word phylla, meaning leaves, is used, and a disepalous calyx is denominated diphyllous, and so on. When sepals are united by adhesion, they form a Gamosepalous or Gamophyllous (γάμος, union) calyx (Fig. 203), terms

implying union of sepals or leaves, and thereforepreferable to monosepalous and monophyllous, which mean literally one sepal or leaf. This adhesion of sepals varies in extent, and thus gives rise to the terms entire, when the union is complete, and there are no divisions at the top, toothed, cleft, and partite, when the divisions are mere toothings, or extend to the middle, or to near the base. Thus, a gamosepalous calyx (Fig. 203), may be five-toothed (quinque-dentate), five-cleft (quinquefid), or five-partite (quinque-partite), the number of divisions usually indicating the number of sepals of which the calyx is composed. In an entire gamose-

Fig. 203. Gamosepalous, five-toothed (quinque-den-tate) calyx of Campion(Lych-

palous calyx the venation assists in the determination of the Botany. number of sepals.

When the union of the sepals is not equal in all the parts, the calyx has an irregular form, as in Labiate flowers (Fig. 204). In the latter case the calyx is two-lipped (bilabiate), the upper lip being composed of three sepals, one of which is either arched or stands out from the rest in a marked manner, and the lower lip being formed of two sepals. The united parts of a gamosepalous calyx form the tube, the free portions at the apex are the lobes or segments of the limb, and the orifice of the tube is the throat (faux).

The tube of a gamosepalous calyx frequently adheres more or less completely to the other whorls, especially to the

Fig. 204. Bilabiate gamosepalous calyx of the Dead-nettle (Lamium), It is composed of two lips, the upper lip formed by three sopals, the lower by two. One of the upper sepals stands prominently out from the

rest.
.. 205. Callyx of Madder (Rubia), adherent to the pistil, its limb appearing in the form of a rim. The callyx is called obsolete.
.. 206. Feathery pappus attached to the fruit of Salsafy (Tragopogon porrifolius). The callyx adheres to the fruit, and its limb is pappose.

pistil. In the latter instance the calyx remains persistent, and forms part of the fruit, as in the Gooseberry. In such instances the limb of the calyx often becomes degenerate, and is either absent, or appears in the form of scales or pointed projections, or of a circular rim (Fig. 205), or of pappus, as in Composite flowers (Fig. 206). In the adherent calyx of Valerian, the limb is at first a ring, but ultimately expands in the form of hairs, and hence is called

The calvx may continue persistent, and yet be separable

from the fruit, as in Henbane,* and in the Peruvian Winter-cherry and other species of Physalis (Fig. 207), where it increases after the flower has withered, and surrounds the fruit like a bladder. It sometimes continues in a withered state, as in the Heath, and is called marcescent. The term superior is applied to the calyx or perianth when it is so united to the fruit as to appear to arise from its summit, as in Melon, and Iris. In the Rose (Fig. 185) the tube of the calyx bears numerous carpels on its concave surface, and the limb at the summit is divided into five segments.

In place of being persistent, the calyx is frequently deciduous, falling off immediately after the flower expands, as in Crowfoot. In the

Fig. 207.

Fig. 207.

Bladder-like calyx of the Winter Cherry (Physalis Alkekengi), laid open to show the mode in which it surrounds the fruit without adhering to it. The calyx is persistent, but not adherent. It enlarges after the flower withers, and is called accrescent.

Poppy* (Fig. 208) the two sepals are detached before the *Pl. CXII. anthesis or the opening of the flower, and they are said to be caducous. In Eschscholtzia,* the calyx is composed *Pl.CXIII. of sepals united together, and joined by an articulation to fig. 6. the thalamus; as the flower expands, they give way at the joint, and fall off in the form of a candle-extinguisher. By the irregular development of one or more sepals, the spurred (calcarate) calyx of Larkspur and of Indian Cress is produced, as well as the hooded or helmet-shaped (galeate) calyx of Monkshood. In Grasses and Rushes the perianth

*Plate

CXXVIII. fig. l.

to find the calyx wholly absent. This, however, occurs in some of the Euphorbias,* in which the flowers are naked (achlafigs. 2 and mydeous), as shown in Figure 209. In these plants there is a series of bracts which at first sight appear to be the calyx; but they are really an involucre inclosing several distinct flowers (Fig. 210). In the Strawberry, Potentilla, and Mallow, the calyx consists of two alternating whorls, the exterior of which has been called Epicalyx, and is by some considered a row of bracts. An epicalyx is also seen in the Carnation. When there is only one floral envelope present, as in Goosefoot (Fig. 178), it belongs to the calycine

whorl, whatever may be

its form or colour.

* Plate

CXXXII.

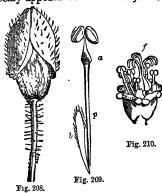

Fig. 208. Caducous calyx of Poppy (Papa-ver). It is composed of two sepals, which fall off before the petals

which fall off before the petals, which fall off before the petals expand.

209. Male flower of Spurge (Euphorbia), consisting of a single stamen, a, without any envelope. The flower is hence called Achlamydeous. The peduncle, a, has a brack, b, at the base, and is united to the flower by a joint at a.

210. Calyx-like (Calyciform) involucre of Euphorbia, unclosing numerous male flowers, and one female flower, f, with three forked styles. The individual flowers are really naked or achlamydeous, in consequence of the floral envelopes being suppressed.

† The Corolla or Inner Floral Envelope.

The Corolla is the inner envelope of the flower, and is composed of a whorl of leaves called Petals (πέταλον, a lamina or leaf), which alternate with the sepals, as seen in Figure 175, and are frequently equal to them in number (isomerous), or some multiple of them. The petals differ from the sepals in being rarely green. They usually exhibit showy colours, and are often odoriferous. Structurally they are composed of cellular and vascular tissue, the latter being spiral vessels and delicate tubes. The epidermis of petals does not in general exhibit stomata, but it sometimes displays beautiful hexagonal and radiating markings under the microscope. It is usually smooth (glabrous), but occasionally coloured hairs occur on it, as in the Bogbean. Petals originate in cellular projections, which are either connected by a ring of cellular tissue, or are separate, according as the parts are ultimately to be united, or to remain distinct. Even when the petals become irregular in after growth, they are equal in the first instance. Some petals continue to increase in size after the flower has expanded.

The forms of petals vary. Sometimes they resemble sessile coloured leaves, as in Crowfoot (Fig. 211); at other

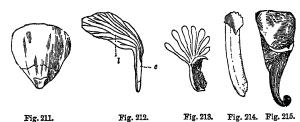

Fig. 211. Petal of Crowfoot (Ranunculus), without a claw, and thus resembling a sessile leaf. At the base of the petal a nectariferous scale is seen.

212. Unguiculate or stalked petal of Wallflower (Cheiranthus Cheiri), c, the claw or unguis; l, the blade or lamina.

213. One of the lateral petals of Mignonette (Reseda). Its blade is cut into numerous segments, and has been called laciniated.

214. Tubular petal of Hellebore (Helleborus), formed by folding and adhesion, in the same manner as pitchers.

215. Horn-like hollow petal of Columbine (Aquilegia vulgaris), formed by folding and adhesion of the edges.

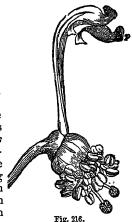

times they are separated into two portions, as in the Wall-

Botany. assumes a glumaceous or scaly appearance. It is very rare flower (Fig. 212), one narrow, c, forming the claw, and the Botany. other broad, I, constituting the limb or lamina. Petals being like leaves, exhibit varieties in their outline or circumscription. In some plants they are split at the apex. so as to be bifid or trifid, or cut into numerous segments (Fig. 213). When a small portion of their apex is deficient they become emarginate and obcordate, and when lobed at the base they are cordate. The apex of petals is sometimes prolonged in the form of a narrow thread, as in Strophanthus, or it ends in a point, which is either straight or

inflexed, as in Umbelliferous plants.* Some petals are folded, *Pl. CXXL so as to assume a tubular or pitcher-like form, as in the fig. 1. Hellebore* (Fig. 214), a spurred form, as in Columbine *Pl. CX. (Fig. 215), Violet, and Larkspur,

a gibbous form, as in Fumitory, or a horn-like aspect, as in the petals under the helmet-shaped sepals of Monkshood (Fig. 216). These anomalous petals sometimes assume a normal form, as in a variety of Columbine, in which the spurs disappear.

When the petals are separate (free and distinct) the corolla is Polypetalous or Dialypetalous (πολύς, many, and διαλύειν, to separate), and the number of the petals is indicated by prefixing the Greek numerals to the term petalous, in the same way as in the case of the sepals; thus, in Figure 217, the corolla is pentapetalous. In the Vine (Fig. 218), in which the corolla is polypetalous, the petals in their early state are united together by their apices, and afterwards separate and fall

Two peculiar horn-like stalked potals, p, of Monkshood (Aconium Nopellus). They are sitted under the helmet-shaped (galeate) coloured sepal, and they consist of a grooved stalk supporting a hollow spurred petal.

off. When the petals are united, the corolla is Gamopetalous or Monopetalous (γάμος, marriage or union, μόνος, one), and the number of its parts is marked by the venation, or by the divisions of the apex, just as in the case of the calyx. Thus, in Figure 219, the corolla consists of five petals united, their number being ascertained by the lobes at the apex, as well as by the midribs. The united portion is called the tube, the divisions are called lobes, and the orifice is the throat (faux). The term limb is often given to the expanded and free part of a gamopetalous corolla.

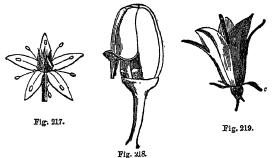

Fig. 217. Polypetalous or Dialypetalous corolla of Biting Stonecrop (Sedum acre). It is composed of five separate petals, and hence is pentapetalous.

- petalons.

 218. The flower of the Vine (Vitis vinifera) in the young state, showing the union of the petals at their upper part, and the mode in which they separate before they fall off.

 219. Regular gamopetalous bell-shaped (campanulate) corolla of Harebell (Campanula rotundifolds). It is composed of five petals united, The ovary is inferior, and is united to the calyx, c.

Some varieties of polypetalous corollas deserve notice. Of the regular forms may be mentioned the rosaceous, as in the Rose and the Strawberry (Fig. 220), in which there are spreading petals, without claws or with very short

the apex to the base, as in the Lily; caryophyllaceous, where

the petals have long, narrow, tapering claws, inclosed in the calyx, as in the Carnation and Pink; cruciferous or cruciate, in which there are four petals, usually with claws (Fig. 212) and arranged in the form of a cross, as in Wallflower (Fig. 176).

Among the irregular forms of polypetalous corollas we may notice the papiliona-ceous (butterfly-shaped) corolla,* as seen in the Pea (Fig. 221), consisting of five parts, differing in size and shape, the upper, st, called *Plate ceous (butterfly-shaped) corolla, * as seen in CXVII. the Pea (Fig. 221), consisting of five parts,

the standard (vexillum), the lower, car, called the keel (carina), formed of two partially-united petals, and the two lateral, a, called wings (alæ). These parts are separately represented in Figure 222, a being the vexillum, b the carina, and c one of the alæ.

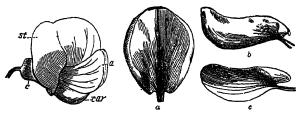

Fig. 222.

a. The vexillum or standard cordate at the base; b, the carina or keel, composed of two petals partially united in a boat-like manner; c, one of the also or wings.

In Monocotyledonous plants the coloured perianths are often polyphyllous, and there is a peculiar irregular kind

which is met with among Orchids. It may be called the Orchideous perianth, and consists of six parts, one of which, called the Labellum, presents many remarkable forms. It is shown in Figure 223, which represents an Orchis, with its labellum, *l*, and a spur, s. The labellum Fig. 223. varies much in form. In Cypripedium it is hollow, like a slipper, and is called calceolate.

Gamopetalous corollas are also divided into regular and irregular forms. In the former the parts are equal in size, and equally united, while in the latter they are unequal in these reFig. 223.

Irregular polyphyllous spurred perianth of Orchis. It consists of six parts, one of which, *l*, called the labellum, differs much from the rest, and gives a peculiar character to the flower A spur, *s*, extends backwards from the labellum. The ovary, *o*, is inferior, *i.e.*, below the divisions of the perianth.

spects. Regular forms are bell-shaped (campanulate), that is, shaped like a bell, and swelling out regularly from base to apex, as in the Harebell (Fig. 219); funnel-shaped (infundibuliform), in which the tube is narrow below, and expands towards the summit, as in Tobacco (Fig. 224); tubular, or nearly uniformly cylindrical, as in some composite flowers; salver-shaped (hypocrateriform), when the limb or lobed portion spreads out at right angles to the tube, which is long, as in Auricula and Primrose; and wheel-shaped (rotate), when a salver-shaped corolla has a

Botany. claws; the liliaceous, where the petals gradually taper from very short tube, as in Forget-me-not (Fig. 225). There Botany.

Fig. 225.

Regular gamopetalous wheel-shaped (rotate) corolla of Forget-me-not (Myo-sotis), consisting of five petals united, with a very short tube. a, corolla entire; b, corolla laid open to show the short tube, the five stamens at tached to the corolla, and the five scales on the petals alternating with the

are also intermediate forms, as in Comfrey, in which the corolla is campanulately-tubular, presenting a combination of the bell-shaped and tubular forms.

Irregular gamopetalous corollas are seen in the lipped (labiate and bilabiate) forms (Fig. 173), in which the union of the petals takes place in such a way as to produce an upper and lower portion, with a gap (hiatus) between them, like the mouth of an animal (Fig. 226). The upper lip is usually com-

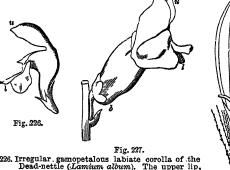

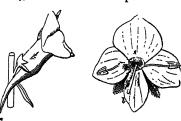

Fig. 226. Irregular, gamopetalous labiate corolla of the Dead-nettle (Lamium album). The upper lip, u, is composed of two petals united, the lower lip, l, of three. Between the two lips (abia) there is a gap (hiatus). The throat is the part where the tube and the labiate limb join. From the arching of the upper lip this corolla is called ringent.

... 227. Personate corolla of Frogsmouth (Antirrhinum majus), showing the gibbous base, b, of the corolla. The lower lip, l, is pushed up on the upper, u, leaving a chink (rictus).

... 228. Irregular gamopetalous ligulate flower of Ragwort (Senecio). It is a tubular floret, split down on one side, with the united petals forming a strap-like projection, L. The lines on the flat portion in dicate the divisions of the five petals. From the tubular portion below, the bifd style projects elightly. The terete fruit (achænium), a, is surmounted by pilose pappus, which is the metamorphosed calycine limb. The flower is female, having no stamens.

posed of two petals, the lower of three. The same form is met with in the calyx (Fig. 204), but the number of parts in the

lips is reversed. A labiate corolla or calyx, with the upper lip much arched, like a helmet (galea), is said to be ringent (Fig. 226). Sometimes the upper lip is very short and nearly wanting, as in Bugle. When

the lower lip is approximated to the upper, so as to leave only a chink (rictus), with a projecting portion below it, -10d the nalate the upper sin Bugle. Fig. 229. Fig. 230. Fig. 230. Irregular gamopetalous personate flower of Snapdragon (Linaria), with a long spur, o (calcar), at the base. 280. Irregular gamopetalous wheel-like corolla of Speedwell (Peronico). The irregularity consists in the different sizes of the lobes of the corolla, especially the lower lobe, t, which is smaller than the rest.

corolla is denominated masked (personate), as seen in Frogsmouth (Fig. 227). In Calceolaria there is a peculiar irregular corolla with two hollow lips. When a tubular corolla is split down on one side (Fig. 228), as in the florets of the

CXXIV.

* Plate

fig. 4.

strap-shaped (ligulate). * Plate

The lower part of some gamopetalous corollas, such as Valerian and Frogsmouth (Fig. 227 b), projects in the form of a bag or sac, and is called saccate or gibbous. Sometimes the projecting part assumes the form of a spur (cal-car), as in Red Valerian, and Snapdragon (Fig. 229). In some gamopetalous corollas there is a very slight irregularity of form. Thus, in Digitalis* the corolla has a somewhat campanulate form, but its development is not equal; the Speedwell (Fig. 230) has a form nearly rotate, but the lobes are unequal; the Bugloss has a funnel-shaped

corolla with a curved tube. In some gamopetalous corollas with a single spur, it happens occasionally, that what are called Pelorian varieties occur in which five spurs are produced. This occurs in common Snapdragon frequently, as well as in species of Frogs-Fig. 231. One of the glumes of Wheat (Triticum), seen in profile. These mouth.

In Grasses and Sedges the arrangement of the parts of the flower is peculiar. In place of verticillate leaves forming the flower, there are alternate scales or glumes. The flowers of grasses usually occur in

spikelets* (Fig. 165), which consist of one or two glumes, a, CXXXVII. covering several flowers, b. In Wheat each spikelet con-

Carices the male flowers are borne on scales, and so are the female, as shown in Figure 235, in which the scale, s, is placed on one side. Within the scale the female flower is situated, having a peculiar bag-like covering, u, termed perigynium.

Abnormalities in the Corolline Whorl.—The parts of the corolla are frequently adherent to those of the calvx. and any change taking place in the latter also causes an alteration in the former. Some of the petals are occasionally suppressed, and sometimes the entire corolla is wanting. The latter occurs normally in apetalous monochlamydeous flowers, such as Chenopodium (Fig. 178); and it also

Botany. Dandelion,* and in the white florets of the Daisy, it is called occurs accidentally. Petals, which are in general coloured, sometimes become green. A corolla, normally gamopetalous, is sometimes divided into separate petals. Flowers become double by the multiplication of the parts of the corolline whorl. This arises in general from a metamorphosis of the stamens. Union of separate flowers (synanthos, σὺν, together, and $dv\theta$ os, flower) occasionally occurs, and the adhesion which thus takes place causes various changes in

> Connected with the inner surface of the petals, there are placed occasionally appendages in the form of scales* or *PI.CXXV.

filamentous processes. These are considered as being modified petals, and they are usually traced to transverse chorisis, in consequence of their being placed opposite to the petals. In many of the Borage order, such as the Comfrey (Fig. 236), Forget-me-not (Fig. Forget-me-not (Fig. 225, b), as well as in the Chickweed tribe, and in the Crowfoot(Fig.211), petaline scales or lamelize of this nature are observed, which, like many other processes connected with the flower, received, in the days of Linnæus, the days of Linnæus, the

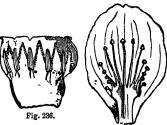

Fig. 237.

name of Nectaries. Peculiar changes in an inner row of petals and in the stamens may also give rise to corolline appendages, as, for instance, the beautiful fringes of the Passion-flower, the crown of the Narcissus (Fig. 149), and the glandular scales of the grass of Parnassus (Fig. 237).

d. Essential Reproductive Organs.

These organs constitute the inner whorls (verticils), and originate, like the floral envelopes,

from the thalamus or torus (the upper part of the axis or peduncle), in the form of minute cellular processes. In their development they resemble leaves, but in general they differ much more in their appearance from the leaves than the floral envelopes do. The essential organs are the stamens and pistil, as shown in Figure 238, where there are five stamens arising from the thalamus,

stamens arising from the thalamus, and surrounding one pistil. The stamens constitute the Androccium, and the pistil the Gynœcium.

These organs are necessary to form a perfect flower, and without them no seed is produced in flowering plants. When, by cultivation, a serial organis (stamens and pistil) of the Vine (Vitite vinifera). There are five simens, with introres two-look anthers, a. Between the anthers at their base are scales forming the dist. The ovary is large, style short, and stigma unidied.

they are changed into floral envelopes, the flower cannot perform its proper functions. These organs are not, however, always present in every flower. When both are present in the same flower, it is Bisexual, Hermaphrodite, or Monoclinous (μόνος, one, and κλίνη, bed), and is marked . When one of the organs only is present, the flower is Unisexual or Diclinous, and is marked 5 2; being called Staminate, male or sterile, when the stamens alone are developed, as indicated by the mark &; and Pistillate, female or fertile, when the pistil only is produced, as indicated by the mark 2. Unisexual Plants, such as the

Botany.

Botany. Hazel and Arum (Fig. 166), in which the staminiferous and pistilliferous flowers are on the same individual, are denominated Monæcious (μόνος, and ὀικίον, habitation), and are marked 5-9; unisexual plants, such as the Willow and Hemp, in which the staminiferous and pistilliferous flowers are on separate individuals, are denominated Diæcious (δις, twice, and δικίον, habitation), and are marked 5:2. In the case of Palms it often happens that, while some flowers are staminate and others pistillate, there are others which are perfect or hermaphrodite; on this account such plants are called Polygamous (πολύς, many, and γάμος, marriage), and are marked 호 5 오 . In all cases in which one of the whorls of the essential organs is absent, it is considered as depending on suppression or non-development; and this view is confirmed by the fact that, in many unisexual flowers, the rudiments of the suppressed organ may be seen, and that in certain circumstances it is developed.

* Andræcium or Staminal Organs.

The stamens are placed immediately within the petals, When there is one whorl the stamens are usually equal in number to the petals, and alternate with them (Fig. 175). When the stamens are twice as many as the petals, they are in two whorls, alternating with each other (Figs. 191 and 192). When there are more than two whorls, each successive verticil alternates with that preceding it. When, in place of being alternate with the petals, the stamens are opposite to them, as in the Primrose, the abnormality is considered as depending, either on the suppression of an outer row, or on transverse chorisis of the petals, or vertical chorisis and union of the stamens.

In cases in which the stamens are not equal in number to the petals, the abnormality may be traced to suppression of a certain number, to abortion, adhesion, or chorisis. In Cruciferous plants there are four sepals, four petals, and six stamens, four of which are longer than the others (Fig. 177). It is supposed that in this case each pair of long stamens is in reality one which has been split by lateral chorisis. This is confirmed by finding teeth only on one side of the filaments of these stamens, while in the two shorter ones teeth exist on both sides, and also by the fact that partial adhesions between them are sometimes seen, as in Streptanthus, and that some cruciferous plants have only four stamens.

A perfect stamen consists of two parts, the Filament (Fig. 239, f), representing the petiole of the leaf, and the Anther

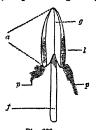

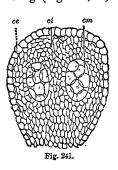

Fig. 239. Stamen with its filament, f, anther lobes, a, connective or union of the lobes, g, suture or line of dehiscence, l, which is longitudinal and lateral, pollen or antherine fertilizing powder, p p.

The communication of the communicati

(Fig. 239, a) analogous to the blade, containing minute cells, in the form of Pollen (Fig. 239, pp). The filament, like the petiole, is sometimes wanting, and the anther is then sessile. The filament is usually articulated to the thalamus, so that the stamen falls off after performing its functions; but in some instances it is persistent and not articulated.

In the filament cellular tissue exists in a condensed form, surrounding a central bundle of spiral vessels, which represents the fibro-vascular system of the petiole. It has a thin epidermal covering, which sometimes presents stomata. Cellular prolongations also occur in the form of hairs, as in

the Virginian Spiderwort (Tradescantia), Anthericum, and Botany. Verbascum, where the stamens are called stupose, and in ' Anagallis tenella, where the hairs have a beautiful knobbed appearance.

The anther, like the lamina of the leaf, is developed before its stalk. It consists originally of a cellular mammilla, containing a mass of thin-walled cells (Fig. 240, ce and ci). In the progress of growth larger cells are produced in the interior (Figs. 241 and 242, cm), forming four separate clusters, each of which is surrounded by a special cellular covering (Fig. 242, cl). These larger cells are destined

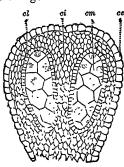

Fig. 241. Vertical section of an anther lobe of the Melon in the progress of growth, showing two large central cells, cm, filled with smaller nucleated cells. The outer epidermal layer, ce; the inner cells, ci, being partially absorbed.

242. Vertical section of an anther lobe of the Melon, showing the two large central cells filled, with other cells, containing polen, cm.

The latter are called mother pollen cells. The two large cells in the centre are now surrounded by a special covering, cl, which constitutes ultimately the endothecium, or inner lining of the anther. The parenchyma, ci, is being absorbed. The outer epidermis, ce, constitutes the exothecum, or outer covering of the anther. The endothecum, and the cells between it and the exothecum, usually contain spiral fibres.

for the formation of pollen, and the four places at which their development commences may be seen on a transverse section of a very young anther. These clusters of pollen cells increase in size, and gradually cause absorption of the surrounding parenchyma. It generally happens that two of the adjacent clusters of pollen cells unite by obliteration of their special covering at one side, and thus ultimately two pollen cavities are found in the anther, in place of four.

In its fully developed state, the anther presents two lobes (Fig. 239, I), like the two halves of the blade of the leaf; these lobes being united by a partition, called the Connective (Fig. 239, g), representing the midrib, and consisting of cells and spiral vessels. Each anther lobe has one or two cavities, which are receptacles of the cellular grains of pollen. These cavities correspond to the large cells seen

in Figure 242, cm, with their special covering, cl, which forms the inner lining of the anther case, called Endothecium (ἐνδον, within, θηκίον, a box or loculament). This lining exhibits elastic spiral fibres, which probably assist in bursting the outer epidermal covering of the anther called Exothecium (E\xi_0, without), corresponding to the cells marked ce in Figures 241

**The control of the state of the control of the cells are the country of the cells are the cells are

Fig. 243.

and 242. In the cells of the endothecium, as the anther approaches to maturity, the membrane becomes sometimes obliterated, so that the delicate fibres alone are left, as is seen in the Melon (Fig. 243), and in Cobæa. These spiral fibres appear also to fill up the space between the two coverings in many full-grown anthers.

Thus the anther represents the lamina of a leaf, with its two halves divided by a midrib, surrounded with a double epidermal covering, the inner being fibro-cellular, and containing cellular tissue which assumes the form of pollen. When there are four cavities (loculi or thecæ as they are called) in the anther, they may be considered as represent-

Botany. ing the two halves of the leaf, each with its upper and lower stratum of cells. This division into four is seen in the young state of anthers, and is considered as the normal state. When it remains in the fully developed anthers they are called quadrilocular or tetrathecal (Fig. 244).

owing to obliteration of some of the partitions, only two loculi remain, as is very generally the case, the anther is bilocular or dithecal (Fig.

It happens occasionally that, by the suppression of one lobe, as in Gomphrena, or by the disappearance of the partition between the two lobes, the anther becomes dimidiate, or onethe divergence of the base of the anther lobes, and their complete union at the apex, render them onecelled (unilocular, monothe-

cal); while in Labiate plants, by the turning of one of the lobes, a union takes place by their bases, so that they form one cavity. The long connective of the Sage and other species of Salvia separates the anther lobes, so that each appears a monothecal anther (Fig. 245), one of which, a, contains pollen, while the other, b, is abortive.

The stamens vary in number, and names are given to flowers accordingly. Thus,-

1 stamen is Monandrous (μόνος, one, and ἀνὰς, male or sta-

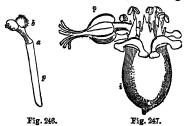

2 stamens is Diandrous (dis, two). Veronica. 3 stamens is Triandrous (egsis, three). 4 stamens is Tetrandous (τετράς, four). Alchemilla. 5 stamens is Pentandrous (afert, five). 6 stamens is Hexandrous (¿ξ, six). Tulip. 7 stamens is Heptandrous (ἐστα, seven). Tries 8 stamens is Octandrous (ἐστὰ, eight). Heath. Trientalis. 9 stamens is Enneandrous (ἐννία, nine). Butomus. 10 stamens is Decandrous (δίαα, ten). Saxifrage. 12 stamens is Dodecandrous (δώδεκα, twelve). Asarum.

20 stamens is Icosandrous ("12001, twenty). Strawberry. Numerous and indefinite stamens is Polyandrous of (making,

In the common Mare's-tail there is only one stamen in each flower, while in Cereus nycticalus 400 have been counted. The number of the stamens determines some of the classes in the Linnar artificial system of classification.

In the case of Euphorbia, flowers are met with, consisting

of a single stamen (Fig. 246), and others consisting of a single pistil. These, when inclosed in one common involucre, or bracteal envelope (Fig. 247, i), seem to be stamens and pistils in the same flower. in the same nower. But on examination it is seen that a joint occurs at a part of the supposed filament (Fig. 246, a), indicating its connection with the peduncle, p, and so also in the

case of the pistil. In some of the species of Euphorbia a proper floral envelope appears at the joint indicating the

true nature of the organ. The flowers represented in Botany. Figure 247 are therefore naked or achlamydeous male and female flowers on one plant, which is therefore said to be monœcious.

The position of the stamens is normally within the petals, and outside the pistil. They arise from the part of the peduncle below the latter, and hence they are Hypogynous, which means under the pistil (υπο, under, and γυνή, female or pistil). But, as in all other parts of the flower, adhesions take place by which changes in apparent position are produced. Thus the stamens, in place of being free and truly hypogynous, sometimes adhere to the tube of the calyx, becoming Perigynous (περί, around), which means surrounding the pistil; while at other times they adhere completely to the ovary, and appear to arise from the top of it, and are hence called Epigynous (ἐπὶ, upon). When the stamens adhere still more completely to the pistil, the union extending above the ovary, they become Gynandrous (γυνη, female, and ἀνηρ, male), as in Orchis, and in Birthwort (Fig. 248), and form with the pistil a column in the centre of the flower.

In place of adhering to the contiguous organs, the stamens may be distinct from them, but united to each other either by their anthers or by their filaments. When the filaments are combined into one mass, more or less completely, the flowers are Monadelphous (μόνος, one, and άδελφὸs, brother), as in the Mallow (Fig. 249); when in two sets or bundles they are Diadelphous, as in Fumitory, and in some papilionaceous flowers, in which the bundles are often unequal, nine stamens being united in one set, and only one (which is superior) in the other (Fig. 250); when in three sets they are Triadelphous, as in St John's Wort; and when in more sets Polyadelphous, as in the Castor-oil plant (Fig. 251). The numerous stamens in the Mallow and St John's Wort, and Castor-oil plant, are by some traced to collateral chorisis, or repeated divisions of the stamens. Sometimes the filaments are united by means of an interposed membrane (a sort of crown), as in the Pancratium. When the stamens are united by their anthers, the flowers are termed Syngenesious or Synantherous (oùr, together, γένεσις, origin, ἀνθηρα, anther), as in Compositæ (Fig. 252), in Violet, and in Lobelia.

Stamens are often shorter than the corolla, and are then said to be included; but at times they elongate and extend beyond it, when they are exserted. In some flowers we find certain stamens constantly longer than others. Thus, in many Labiate flowers (Fig. 253), and in Frogsmouth, we meet with two long and two short stamens, the flowers being Didynamous (ois, twice, and ouvajus, superiority), and in Cruciferous flowers there are four long and two short (Fig. 177), the flowers being Tetradynamous (respás.

four, δύναμις, superiority). Stamens in general stand regu-Botany. larly round the pistil, but occasionally their upper portions

are curved to one side of the flower, and they become declinate, as in the Amaryllis and Horse-chestnut.

The filament is slender and cylindrical, or slightly flattened. It is curved and elastic in the Pellitory (Fig. 254)

Fig. 255. Fig. 256.

257. Adnate anther of Barberry (Berberis unigaris). The lobes of the auther open by hinged valves.

and in the Nettle, petaloid in the White Water-Lily, and in Indian Shot and Ginger, broadened at the base in Campanula, thickened in Barberry (Fig. 257), with appendages in Borage (Fig. 255) and Asclepias (Fig. 256). The filament is attached to the anther lobes, either by adhering along their whole length on one side, called the back, and the anther is then adnate, as in Magnolia, Crowfoot, and Barberry (Fig. 257); or it extends only to the base of the lobes, which are firmly fixed to it, and the anther is innate, as in Carex (Fig. 258), or its apex is attached to a single point of the anther, which then swings easily about, and is called Versatile, as in Grasses (Fig. 165).

The anther presents a groove or depression between its lobes, indicating the place where the septum or partition is situated (Fig. 239, g). Each anther lobe also presents a line or furrow running from top to bottom, and placed more or less laterally. This is called the Suture, or line of dehiscence, and marks the place where the anther opens to discharge the pollen (Fig. 239, 1). The suture corresponds to

the edge of the leaf, and in innate anthers it is lateral, Botany. while in others its position is more or less distinctly on the face of the anther, or on the side opposite to the attachment of the filament. At the suture the epidermal tissue is thin, and the endothecium is wanting.

The face of the anther is usually directed towards the centre of the flower, in which case the anther is called Introrse, as in the Vine (Fig. 238); at other times it is directed towards the circumference of the flower, and the anther is Extrorse, as in the Meadow-saffron and in the Iris. The mode of opening or of dehiscence varies in different anthers. Sometimes the lobes split along the whole face, either in the centre or at the side, longitudinally (Fig. 239), at other times transversely (Fig. 259). Sometimes the slit

262. Two stamens of Pansy (Viola tricolor), with their two anther lobes, and the process, p, extending beyond them. One of the stamens has been deprived of its spur, the other shows its spur, c.

only takes place at the apex, so as to present two holes or pores, as in Rhododendron and Solanum (Fig. 260), or four pores, as in Poranthera, or two tubes, as in the Heath, or so as to form a separable lid, as in Gamboge. In the Barberry, each lobe of the anther opens by a single valve, which is rolled upwards (Fig. 261, v); and the same thing occurs in many Lauraceæ, in which, however, there are frequently four valves, that is, two to each lobe, corresponding to the antherine cavities.

The union of the anther lobes is effected either by a continuation of the filament (Fig. 257), or by a mass of cellular tissue with spiral vessels, called the Connective (Fig. 238). This extends to a greater or less height between the lobes, and is sometimes so narrow as to be inconspicuous, as in Euphorbia. Sometimes it reaches beyond them in the form of a cellular expansion, as in Magnolia, Violet (Fig. 262, p), and Asarum, or of a long feathery appendage, as in Oleander; while at other times it proceeds backwards in the form of a spur, as in the Violet (Fig. 262, c), and in the Heath. It divides into two branches occasionally, each bearing an anther lobe, as in Sage (Fig. 245), and then it is distractile.

The Pollen-is contained in the anther, and presents the appearance of a minute, usually yellow powder, which,

Pollen grains of Melon (Cucumis Melo) in various stages of development. No. 1, the grains in a young state, and free; No. 2, the grains farther advanced, and nearly ripe; No. 3, a pollen-grain in a ripe state, fully developed.

Botany.

Botany. when examined by the microscope, is found to consist of cellules (Fig. 263) of different forms, varying from 300th to That of an inch in diameter. Pollen-grains, when fully formed, are usually spherical, oval, or triangular (Figs. 267, 268, 269). In Podostemon the pollen is of an oblong shape, with an hour-glass contraction in the middle; while in Zostera it consists of long slender threads.

Pollen-grains are developed in the large cells seen in the early state of the anther (Figs. 241, 242, cm). Each of these cells is called a parent or mother cell (Fig. 264, cm). Its contents divide first into two, and then into four parts, each of which becomes covered with cellulose, so as to constitute an independent cell or pollen-grain (Fig. 264, p). These grains either burst through the parent cell and become free, or they remain united in fours or some multiple of four, as in many species of Acacia; or in large masses, such as those seen in Orchids (Fig. 265), and in Asclepias, where they constitute *Pollinia*. The remains of the partially destroyed mother cells sometimes remain in the form of threads.

Each pollen-grain has usually two coverings, the outer called Extine, being a firm membrane marked frequently

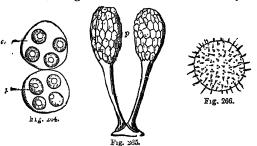

Fig. 264. Parent cells, cm, from the anthers of the Melon, each containing four grains of pollen, p. The parent cell divides first into two by a merismatic process, and then each of these parts subdivides into two, thus forming four cells. The grains of pollen are represented with nuclei in their interior.

with nuclei in their interior.

265. Pollinia, or pollen-masses, separated from the point above the stigma, with their retinacula or viseld matter attaching them at the base. The pollen-masses, p, are supported on stalks or caudicles. These masses are easily detached by the agency of insects.

266. Round ripe pollen of Hollyhock (Alexa), with its extine covered with prominent points.

with bands, reticulations, or rough points (Fig. 266); the inner, denominated Intine, being thin and capable of extension. The intine alone is present in Zostera. In the ripe pollen of the Fir (Fig. 267) the distension of the intine is such as to separate the extine into two hemispherical

In the interior of pollen-grains a minute granular matter exists called Fovilla, mixed with starch and oily matter. The fovilla granules vary from 4000th to 30000th of an inch in diameter. These display motions which are looked upon by some as molecular, or such as are seen under the microscope among minute particles suspended in fluid; while by others they are regarded as analogous to the phytozoic movements seen in the antheridia of Cryptogamic plants.

Fig. 269.

Fig. 267. Pollen of Fir (Pinus), in which, by the increase of the intine, the extine is separated into two hemispherical portions, marked by the dark spaces are acade end of the grains.

268. Rips rounded pollen of Cherry (Cerasus), discharging its fovilla through a tubular opening formed by the intine. There are other two points at which the intine is seen protruding.

269. Triangular pollen of Evening Primrose (Exothera), with one pollen tube, t. protruded. This tube is formed by the intine, which is also seen projecting at the other angles.

The surface of pollen-grains is often marked by grooves or folds, or by rounded markings. At these parts the extine is either deficient, or separates like a lid, as in the Passion-flower. When the pollen is moistened in water its grains absorb it and become enlarged, and the intine bursts at one or more points, sending out the fovilla (Fig. 268). When the pollen is scattered on the pistil, and is moistened on one side by the fluid of the stigma, the intine, in place of bursting, protrudes in the form of a tube called a pollentube (Fig. 269, t). The number of tubes protruded in different kinds of pollen-grains varies.

Transformations of Stamens.—Changes take place in the stamens by suppression and degenerations of various kinds. Whenever the stamens are below the number of the parts of the calyx, we may suspect that there has been some suppression. In many irregular flowers, such as Figwort and Dead-nettle, four stamens only occur, although the parts of the calyx and corolla are five. This depends on the suppression of one stamen, and in the case of Figwort we find a rudimentary stamen in the form of a staminodium attached to the corolla on the upper side. Again, in allied plants, such as Pentstemon, the fifth stamen is produced. stamens are suppressed in the case of pistilliferous flowers. In flowers with numerous stamens, such as Poppies, Roses, and Crowfoots, there are always some of the stamens abortive, for we do not find two flowers in which the number is the same. It seems to be a law in vegetable organography that the number of the floral organs is less constant the greater it is. Stamens in some plants have a great tendency to be changed into petals, especially in cultivation. When the anther is abortive the filament sometimes produces hairs in its place. In the case of Canna, where only one anther lobe is perfected, the filament becomes petaloid. It is probable that the peculiar gland-like scales of Parnassia are only an altered state of the stamens (Fig. 237). Occasionally the anthers are converted into carpels.

The Disk.—The organ which botanists call the Disk seems to be in many cases an alteration of some of the staminal whorls. This is more especially true of such cases

as Gloxinia and Gesnera, where the scales alternate with the developed row of stamens, and wherethe fifth stamen assumes the form of a scale. The Disk may be said to consist essentially of processes arising from the thalamus between the developed stamens and pistil. In the Orange the disk is in the form of a ring surrounding the base of the pistil; so also in Rue, where it is very large and conspicuous. In the Vine (Fig. 238), the disk-scales are evident. In the Tree Pæony (Fig. 270) the disk forms a dark red expansion which covers the follicles. In Umupper part of the fruit.

Fig. 270. Flower of Tree Pæony (Moutan officinalis), deprived of its corolla, and showing the disk in the form of a fieshy expansion covering the ovary.

belliferous plants,* the remains of the disk are seen at the *Pl.CXXL

† Gynæcium or Pistilline Organs.

** Pistil before becoming the Fruit.

The pistil is the verticil which terminates the axis of growth, and is placed in the centre of the flower. It is composed of leaves called Carpels or Carpidia (καρπὸς, fruit), from their connection with the fruit. These leaves are folded, so that their lower surface is external, and they are well seen in the Cherry, with double flowers, in which the organs of reproduction are more or less completely altered. In this plant one or more leaves (Fig. 271) occupy the place of the pistil. When there is a single carpel (Fig.

Botany. 272), the pistil is Simple, and the two terms (carpel and pistil) are synonymous; when there is more than one carpel, the pistil is Compound (Fig. 273, c). The carpels are either distinct or united; and it frequently happens, that by adhesion and obliteration, changes take place by which

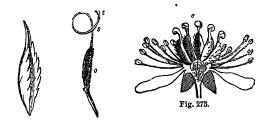

Fig. 272.

Fig. 271. Fig. 272. Fig. 272. Fig. 272. Fig. 272. Fig. 271. Folded carpellary leaf of the double-flowering Cherry. In place of fruit the plant produces leaves.

... 272. Fistil of Broom, consisting of overy, o, style. s, and stigma, t. It is formed by a single carpel. The terms pistil and carpel are here synonymous.

273. Vertical section of the flower of Meadow-sweet (Spiraza). The pistil is apocarpous, consisting of several distinct carpels, c, each with ovary, style, and stigma. The stamens are indefinite, and inserted into the calyx.

the number of the carpels is diminished, so that they do not equal the other whorls. It is rare to find the parts of the pistilline whorl symmetrical with the others. A flower, however, is still called symmetrical if the numbers of the three outer whorls are equal to or multiples of each other.

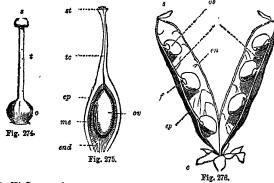

Fig. 274. Compound syncarpous pistil of Primrose (Primula). The five carpels of which it is composed are completely consolidated so as to appear one. The ovaries, o, the styles, t, and stigmata, s, are united. The flower is salled Monogynous, although in reality there are five parts of the pistil.

275. Pistil of Apricot (Pramus Armeniaca), cut vertically. The sollitary ovule, ov, is contained in the ovary, which consists of three coats, the inner, end, which corresponds to the upper epidermis of the carpellary leaf, and which finally becomes the hard stone of the Apricot. The middle, me, corresponding to the mesophyllum or parenchyma of the carpellary leaf, and which illulimately becomes the fieshy part of the Apricot; and the outer, ep, corresponding to the lower epidermis of the carpellary leaf, and which inhally constitutes the separable skin of the Apricot. The style is prolonged upwards, containing a canal, te, and ending in the stigms, st, consisting of loose cellular tissue uncovered by epidermis.

276. Pistil of the Pea (Pisum sattivum), laid open. It consists of a single carpel containing numerous ovules, eu, which are attached to the placenta, pl, or ventral suture in two rows, by means of umbileal cords (funicull), f. The wall of the carpel consists of three layers, the outer, ep, corresponding to the lower epidermis of the leaf. Between these two layers there is a small amount of cellular tissue like the parenchyma of the leaf. The parenchymators portion is not so much developed as in Figure 275. The calyx, e, is persistent. The style and stigma are marked s.

A pistil is called Apocarpous or Dialycarpous (ἀπὸ, separate, διαλύειν, to separate, and καρπός, fruit) when all the carpels are separate (Fig. 273); and Syncarpous (où, together or united) when they are combined into one (Fig. 274). The parts of a perfect pistil are the Ovary, containing ovules or rudimentary seeds, the Style, and the Stigma. These terms are rather vaguely used, as applying either to the parts of a single carpellary leaf, or to the parts of a pistil formed of more than one carpel, and in which the ovaries, styles, and stigmas are united completely. In Figure 275 the lower portion is the ovary containing the ovule, ov, the style is marked to, and the stigma st. The style is not always present, and, when absent, the stigma is Botany. sessile, as in the Poppy.*

The ovary of a simple pistil consists of the folded blade *Pl. CXII. of a single leaf (Fig. 276), and resembles it in structure fig. 2. The outer surface of the ovary (Figs. 275 and 276, ep) represents the lower epidermis of the leaf, sometimes covered with hairs, and, when green, exhibiting stomata; the inner surface (Fig. 275, end, and 276, en) represents the upper epidermis; between these surfaces are placed the parenchyma, and the vascular tissue consisting of woody, spiral, and dotted vessels of various kinds (Fig. 275, me). The midrib is on the outer or dorsal surface, and therefore is inferior, while the two edges of the leaf (Fig. 276, pl) are united at their inner part or face next the axis, and are superior.

The face of the ovary is called the ventral suture, while the back is called the dorsal suture. At the ventral suture there is a cellular growth called the Placenta (Fig. 276, pl), to which the ovules, ov, are attached often by a distinct cord, f. As each margin of the folded leaf or carpel forms a placenta, this organ is essentially double, and it sometimes shows its formation by appearing as two lamellæ (Fig. 276, pl). Along the placenta the ovules are placed in one or more rows. Sometimes they occupy a small part of the placenta, as in cases where they are reduced to one (Fig. 275) or two. The parenchymatous tissue sometimes becomes hard, as in the nut; at other times it is much developed, and forms a succulent covering, as seen in fleshy fruits (Fig. 275, me).

When the style exists, it is a prolongation of the cells and vessels of the leaf upwards, and represents the narrow portion of an acuminate leaf, folded so as to form a canal (Fig. 275, tc), with loose cells inside. It is terminated by the stigma (Fig. 275, st), which is a loose cellular portion divested of epidermis, and moistened with fluid, so as to detain the pollen-grains when scattered. The stigma is sometimes a mere point, at other times it extends along one or both sides of the style. It is to be considered as continuous with the placenta.

When the pistil is formed of a single carpel, it terminates the axis, and appears to be continuous with it. When the pistil is bicarpellary, that is, formed of two carpels, they are placed opposite to each other, and if they unite, it is by their ventral sutures. The carpels, in such a case, are usually placed so that one is superior, that is, next the axis, and the other inferior, next the bract of the axillary flower, as in the Figwort order. Sometimes, however, they are lateral, that is, to the right and left of the axis in a plane at right angles to the axis and bract, as in the Gentian order, and Cruciferæ. When the carpels are more than two, they follow the usual laws of alternation with the other parts of the flower. It is chiefly in apocarpous pistils that the alternation can be satisfactorily seen; for in syncarpous pistils the adhesion which takes place often obscures the arrange-

The number of carpels in an apocarpous pistil, or the number of separate styles in a syncarpous one (i.e., one in which the ovaries are united), is indicated in the following way:—A flower with a simple pistil or one style is Monogynous (μόνος, one, and γυνή, female); with two separate carpels or two separate styles, Digynous; with three, Trigynous; with four, Tetragynous; with five, Pentagynous; with six, Hexagynous; with seven, Heptagynous; with eight, Octogynous; with nine, Enneagynous; with ten, Decagynous; with twelve, Dodecagynous; with a greater number, Polygynous. These differences are employed by Linnæus in forming some of his Orders.

In an Apocarpous pistil, the carpels may be arranged in one circle (Fig 273), or in several (Fig. 277). In the latter case, the inner whorls alternate in succession with the outer. Sometimes they are placed on a flattened receptacle or thalamus, as in Marsh Marigold; at other times on an

Botany. elevated one, as in the Crowfoot (Fig. 277), and in the Strawberry (Fig. 184); while at other times they are placed on a concave one, as in the Rose (Fig. 185).

In a Syncarpous pistil, various degrees of adhesion take place. The carpels may unite merely at their inner angles, leaving marked external divisions, as in the Rue; or the ovaries may be completely united while the styles are separate, as in Flax (Fig. 278); or the whole may be conso-

Fig. 278.

Fig. 278. Apocarpous compound pistil of Crowfoot (Ranuculus), consisting of numerous separate uni-ovalar carpels, arranged in several rows on an elevated receptacle. The flower is polygynous. Each carpel consists of ovary, style, and sugma. Two of the stamens are left to show their insertion below the pistil into the thalamus. The stamens are hypogynous, and the plant belongs to Thalamifloræ.

278. Syncarpous pistil of Flaz (Lumm). It consists of five carpels, united by their ovaries, while their styles and stigmas, s, are separate. Hence, the flower is pentagynous.

279. Ovary or lower part of the pistil of the Lily (Lilium), cut transversely. There are three localements, indicating the union of three carpels, and the ovary is said to be trilocular. The divisions in the ovary, called septa or dissepiments, are formed by the sides of the carpellary leaves. Each septum is double, and the number of septa ocresponds with the number of the carpels. The ovules are placed collaterally, in pairs, in each localament, and are attached to a central placenta, formed by the union of the three ventral sutures.

lidated into one, as in the Primrose (Fig. 274). In rare cases the styles and stigmas are united into one body, while the ovaries are separate, as in the Labiate and the

Borage orders.

In syncarpous pistils, the number of carpels entering into their composition may be traced by observing the grooves or lobes of the ovary, by the number of styles and stigmas, and, when complete union takes place, by the venation, or by the divisions seen in the interior of the ovary. Thus, in the Lily, the syncarpous pistil is composed of three carpels united, and, by cutting across the ovary (Fig. 279), we observe three loculi containing ovules. The carpels are generally united in such a way, that partitions or dissepiments (septa), more or less complete, are seen on making a transverse section. These are formed by the union of the margins or sides of the carpellary leaves, each septum being essentially double or composed of the laminæ of two contiguous carpels. The septa of collateral carpels are therefore vertical, and equal to the number of carpels. There can be no true septum in a single carpel, but spurious divisions (phragmata) may be formed, either in a transverse manner by cellular processes proceeding from the walls of the carpel, as in Cassia Fistula and Desmodium; or in a vertical manner, by projections from the dorsal suture, as in Flax; or by prolongations of the placenta, as in Cruciferæ, where a replum is produced; or by a turning inwards of the ventral suture, as in some species of Oxytropis, or of the dorsal suture, as in Astragalus. In the Thorn Apple, the ovary, when cut transversely at the upper part, shows two cavities; but when the section is made at the lower part of the ovary there are four cavities formed by a spurious vertical septum.

When the partitions in the pistil extend to the axis, a transverse section shows a number of contiguous cavities or Loculaments (loculi), with the placentas in the centre bearing ovules (Fig. 280). A compound pistil of this sort composed of two carpels is two-celled (bilocular); of three, threecelled (trilocular), as seen in the Lily (Fig. 279); of four, four-celled (quadrilocular); of five, five-celled (quinquelocular), as in Campanula (Fig. 281); of many, without distinct reference to number, many-celled (multilocular or

plurilocular). In these cases the placenta is in the centre, but Botany. still connected with the walls of the ovary by means of septa.

When the partitions do not extend to the centre, all the cells or loculi communicate, and hence such a compound pistil is really unilocular, or has one cavity, as in the Poppy and Orchis (Fig. 282). In these unilocular syncarpous

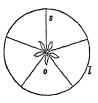

Fig. 280.

The ovules, o, are attached to a central placenta, formed by the union of the five ventral sutures. The five partitions, septa or dissepiments, s, are composed of the two sides of contiguous carpels. Dorsal suture, I.

281. Ovary of Bell-flower (Campanula), cut transversely. The placenta is in the centre, consisting partly of a prolongation of the axis in the form of a column, and partly of the true placentaries, bearing numerous ovules, arranged collaterally in pairs. The ovary is quinquelocular, being formed by five carpels, which are attached to the calyx, s. The back of each of the carpels corresponds to the midrib, s, of a sepal.

282. Unifocular or monothecal ovary of an Orchid (Orchis), cut transversely, showing three parietal placentas bearing ovules. The edges of the carpels are slightly folded inwards.

pistils there may be seen partitions proceeding to a greater

or less extent into the cavity of the ovary, and bearing placentas on their No edges. Such placentas are called Parietal, and their number indicates the number of united

number of united carpels. These placentas are sometimes nearly sessile on the walls of the ovary (Fig. 283), at other times they are supported on distinct parietal septa (Fig. 284). Suchare called 284). Suchare called support of the carpels of the carpels are applied to each other in a valvular manner.

185. 283. Diagramatic section of a quinquelocular ovary, in which the edges of the carpels are applied to each other in a valvular manner.

284. Diagramatic section of a quinquelocular ovary is unilocular, and the compound ovary is unilocular, and the placentas and ovules, o. In the compound ovary, in which the edges of the carpels are parietal, and the ovules appear sessile on the walls of the ovary. Supplied to each other in a valvular manner.

284. Diagramatic section of a quinquelocular ovary, in which the edges of the carpels bearing the placentas and ovules, o, are not folded inwards. The placentas are parietal, and the ovules appear edges of the carpels ovary, in which the edges of the carpels are applied to each other in a valvular manner.

284. Diagramatic section of a quinquelocular ovary, in which the edges of the carpels are applied to each other in a valvular manner.

285. Diagramatic section of a quinquelocular ovary, in which the edges of the carpels are applied to each other in a valvular manner.

286. Diagramatic section of a quinquelocular ovary, in which the edges of the carpels are applied to each other in a valvular manner.

287. Diagramatic section of a quinquelocular ovary, in which the edges of the carpels are applied to each other in a valvular manner.

cases of parietal placentation, and are considered as showing the formation of marginal placentas, on the edges of carpellary leaves more or less completely folded inwards towards the axis. The ovules, in these instances, are analogous to buds on the margins of leaves, as seen in Bryophyllum (Fig. 141).

Cases occur in which the carpels are united so as to have

no apparent folding inwards of their edges, and in which the placentas are placed in the centre, quite separate from the walls of the ovary, as in the Chickweed and Primrose families. This is called Free Central placentation (Figs. 285 and 286). It is by some considered as being produced by the disappearance of

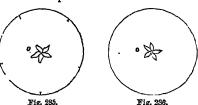

Fig. 285. Fig. 286.

Fig. 285. Diagramatic section of a compound unifocular ovary, formed by five carpels, the edges of which are very slightly folded inwards, as represented by short lines on the inner surface of the circle. The ovules, o, are in the centre, and not attached to the walls of the ovary.

286. Diagramatic section of a compound unifocular ovary, in which there are no indications of partitions. The ovules, o, are attached to a free central placenta, which has no connection with the walls of the ovary.

the septa, or by their rupture, at an early period of the growth of the ovary, so as to leave the placentas in the

Botany. middle. This view is strengthened by seeing in some of the Chickweed tribe septa in a very early stage of growth, and imperfect remains of these partitions on the wall of the ovary, even in an advanced stage (Fig. 285). some instances, however, especially in the Primrose tribe, no vestiges of septa are found, and no marginal ovules at any period of growth (Fig. 286). Hence this kind of free central placentation is supposed to be produced by a prolongation of the axis, and it is therefore denominated Axile—the leaves of the gynocium being looked upon as united in a valvate manner, and as being verticillate round the placentary axis, which bears ovules like leaf-buds. Those who adhere to the view of all placentas being formed on the margins of leaves, have endeavoured to account for cases of free central placentation like those of the Primrose, by considering the placenta as formed by chorisis from the edge of carpellary leaves, or by placentas produced only at the base of the carpel, and, after uniting together in the centre, becoming elongated and enlarged. On the other hand, some advocates of axile placentation not only apply this view to such cases as those of the Primrose, but to all cases of placentation whatever; and, in the case of parietal placentas, think that the axis divides into a number of cellular prolongations, which become attached to the edges of the carpellary leaves.

Marginal placentas are formed either by the edges of a single carpel, or by the edges of two contiguous carpels. The former takes place in apocarpous pistils (Fig. 276, pl), and in syncarpous pistils with complete septa (Fig. 287); the latter in syncarpous pistils with parietal placentas (Fig. 282). The placenta does not always bear ovules throughout its whole extent. Sometimes it is ovuliferous (ovule-bearing) only at or near its summit, Pistil of Meadow-saffron (ovule-bearing) only at or near its summit, Pistil of Meadow-saffron or in its middle or at its base. In such placentas the ovules are sometimes reduced to one, as in the Common Seablucenta in Composite plants. The placenta in some instances extends from the margin of the carpellary leaves over the whole inner surface of the ovary, as in the Flauweing Rush and in the White Water-Lily. The in the Flowering Rush, and in the White Water-Lily. The

Fig. 287.

spreading of the placenta over the surface may give rise to the appearance of ovules proceeding from the dorsal suture, especially when that is the only part of such a placenta which bears ovules.

The carpellary leaves forming the pistil or Gynoccial verticil are usually sessile, but cases occur in which they appear to be stalked so as to raise the ovary. Such an occurrence may be considered as depending either on a prolongation of the axis supporting the pistil, as seen occasionally in certain monstrosities of Rose and of Geum, or on the union of the petioles of carpellary leaves. In the Passion-flower, there is a distinct stalk or gynophore (yvv), temale, and φορέειν, to bear), bearing the pistil. The same thing takes place in some of the Caper tribe, as well as in Lychnis, in the Pink, and in Dictamnus (Fig. 182), where the stalk is short and thick.

When the pistil is free in the centre of the flower it is called superior, and the other verticils are inferior or hypogynous. It is often united to the calyx and the other whorls. When the adhesion between the ovary and calyx or perianth is complete, as in the Gooseberry, the ovary is said to be inferior. In such instances, the petals and stamens, which are attached to the calyx, appear to arise from the summit of the ovary, and are called Epigynous (en, upon, and yuvi, pistil). Between these two conditions, there are intermediate stages of adhesion, as seen in some Saxifrages, where the ovary becomes half-inferior.

In certain cases it has been supposed that the axis forms

part of the walls of the ovary by spreading out in a concave Botany. manner, in the same way as the expanded axis of Eschscholtzia* seems to form part of the calyx. In the Rose the *Pl. CXIII axis becomes united to the tube of the calyx (Fig. 185), fig. 7. and is prolonged so as to form a hollow cavity or disk, on the inside of which numerous separate carpels are placed.

The Style—is the prolonged apex of the carpellary leaf, and is not an essential part of the pistil. In some cases it seems to be a process from the placenta, as shown by Lindley in Babingtonia. It may, therefore, consist merely of cellular tissue, with spiral vessels, or it may also have woody

tubes and other vessels of the midrib and blade of the leaf entering into its composition. A canal traverses it (Fig. 275, tc), containing loose cells, called conducting tissue, which is continuous with the placenta. The style (Fig. 274, t) is situated at the proper apex of the leaf (apicilar), but, by changes in the direction of the apex, it frequently happens that the style appears to be lateral, as in the Strawberry, or even basilar, i.e., from the apparent base, as in Lady's-mantle (Fig. 288). In syncarpous pistils the styles are frequently united, so as to appear single (Fig. 274). When the carpels are placed round an enlarged axis, so that their apices are united to the summit of it, the styles, when united, appear to come from the axis of the plant, as in many of the Borage order, and in the Sage. The carpels are called in such cases Gynobasic (γυνη, pistil,

and βάσιs, foot). In the Geranium the styles are united to the prolonged axis or beak, from which they separate

when the fruit is ripe (Fig. 183).

The style in its form is generally rounded, but at times it becomes flat, like a petal, as in Indian-shot. In the Bell-flower there are peculiar hairs on the style, apparently connected with the application of pollen. The style in the pistil of Clematis is also hairy, so as to render the fruit caudate or tailed. A style, apparently simple, may be formed of several united. Frequently the divisions of such a style extend downwards for a certain length, showing the parts of which it is composed, and thus indicating the number of carpels. But there are cases in which the style, proceeding from a single carpel, actually splits into two parts, becoming forhed, as in Euphorbia. This splitting is accounted for by the circumstance that the style is in reality double, formed of two sides of the leaf.

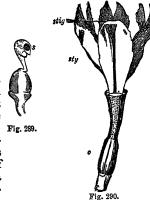

The Stigma—is a part of the pistil, composed of loose cells, which secrete a viscid fluid, and which are uncovered by epidermis. This organ is either sessile on the summit of the ovary, as in the Tulip and Poppy, or it is placed at the apex (Fig. 274, s), or on the side of the style. It may be said to be continuous with the placenta, differing from it in not bearing ovules. This connection with the placenta is evidently seen in cases where it can be traced along one or both sides of the style as far as the ovary. Being formed like the placenta, the stigma is essentially double, and sometimes shows a division on one side, as in Drosera and some Euphorbias. The half of one stigma occasionally unites to the half of that next it, thus giving rise to a peculiar abnormality in the relation of the parts.

Stigmas in a syncarpous pistil are either united or free. In the latter case their lobes or lamellæ indicate the number of carpels. The united stigmas sometimes become large and orbicular, as in Rock-rose, or capitate, as in Primrose (Fig. 274, s), or they radiate along a shield-like body, as in the Poppy.* In the Periwinkle the stigma is covered *PI. CXII with hairs, and exhibits a marked contraction in the middle like an hour-glass, with a broad rim below. In the Nettle the stigma is covered with hairs radiating from a point, and

Botany. is called penicillate. In the Violet (Fig. 289, s), the stigma has a hooded and

hooked appearance.

The name of stigma is sometimes erroneously given to parts of the style. Thus the upper petaloid portions of the style of the Iris (Fig. 290, sty) have been called stigmata, a term which ought to be restricted to the little slits at their apex (Fig. 290, Fig. 289. stig). So also the umbrellalike stigma of Sarracenia is in reality an expansion of the styles with the stigmata at their edges. In some stigmata, as those of Mimulus, the two lamellæ are irritable, and close when touched. In Orchids the stigma is sessile on the common column (gynostemium, $\gamma \nu \nu \dot{\eta}$, pistil, and $\sigma r \dot{\gamma} \mu \omega \nu$, stamen), and appears as a viscid space immediately below the anther lobes. at their edges. In some stiglobes.

Transformations of the Pistil.—These are of frequent occurrence, and depend, generally, on abortion of a certain number of carpels, and on adhesions of various kinds. In the apocarpous pistils of Aconite, Nigella, Larkspur, and Pæony, we find on the same plant pistils composed of two, three, four, five, and six carpels. In some of the Brambles, Moquin-Tandon has seen all the carpels except one disappear, thus making the fruit resemble that of the Plum. In the case of Leguminous plants, there is usually only a single carpel, although the flower is pentamerous; this state has been traced to abortion of carpels, and the view is confirmed by finding plants in the same natural order with more than one carpel. Pistils of a succulent nature, such as those of the Sloe and Bird-cherry, sometimes assume the form of a pod, like that of the Pea. Occasionally stamens are changed into carpels, and at other times the carpels are transformed into stamens, and bear pollen.

The Ovule—is the rudiment of the future seed (Fig. 275, ov), and in its early state it appears as a minute cellular projection or mammilla of the placenta. It is analogous to a bud produced on the edge of a leaf, or to a bud formed on a branch in cases where the placenta is axile. The cells multiply until the ovule assumes a more or less enlarged ovate form, constituting what has been called the Nucleus, or the central cellular mass of the ovule (Fig. 291, n).

The ovular nucleus alters in the progress of growth, so as to be prepared for the development of the embryo plant in its interior. At the apex of the nucleus an absorption or obliteration of cells takes place, by which a hollow cavity is formed, which becomes lined with a thin cellular membrane (epithelium), and forms the sac in which the rudiments of the embryo first appear (Fig. 292, s). This embryo-sac is surrounded by a cellular layer derived from the nucleus (Fig. 292, n), to which the name of Tercine has been given. In some instances the tercine appears to be the only covering of the sac, as in the Mistleto. In most cases, however, other cellular layers are formed, which first appear in the shape of annular appendages at the base, and then gradually spread over the central mass. These ovular coverings are usually two, one next the nucleus, and first formed (Fig. 293, s), called the Secundine, and the other on the outside (Fig. 293, p), called the Primine. These two coats or coverings of the ovule are sometimes incorporated so as to appear one.

At the base of the ovule these coverings and the nucleus Botany. are intimately united at one point by a cellular and vascular process, called the *Chalaza* (Fig. 292, ch), where the

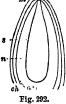

Fig. 291. Young ovule of Celandine (Chelidonium majus) before its coverings are developed. It consists of the nucleus, n, which at this stage of growth is naked. The base of the nucleus, where the nourishing vessels enter, is marked ch. This point is called the chalaza.

... 292. Orthotropous or Orthotropal ovule of Polygonum, showing the embryo-sac, s, in the nucleus, n, the different ovular coverings, the base of the nucleus or chalaza, ch, and the apex of the ovule with its foramen. m.

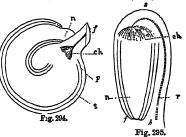

oase of the futeres of chalaza, or, and the apex of the overle with its foramen, m.

293. The ovule of Polygonum, with its nucleus, n, covered by the inner coats, s, or the secundine, and the outer coats, p, or the primine. The opening in the secundine, end, is called the endostome, that in the primine, ex, is the exostome. The point of the nucleus is seen projecting at the foramen. The end by which the ovule is attached to the placenta is marked f.

nourishing vessels enter from the placenta. At the apex of the ovule they leave an opening called the Foramen or Micropyle (μίκρος, small, and πύλη, a gate), through which the influence of the pollen is afterwards conveyed. This foramen extends through both ovular coats, the opening in the outer (Fig. 293, ex) being the Exostome (εξω, outside, and στόμα, mouth), and that in the inner (Fig. 293, end) being the Endostome (¿vôov, within). The foramen indicates the organic apex of the ovule, while the part connected with the placenta by means of the stalk (Fig. 293, f) called the Funiculus or Podosperm (ποῦς, a foot, σπέρμα, a seed), is the base or Hilum.

The relation which the hilum, the micropyle, and the chalaza bear to each other, varies in different ovules. In an Orthotropous (ὀρθὸs, straight) or straight ovule (straight as regards its axis), the chalaza is at the hilum, and the micropyle at the opposite extremity (Fig. 292). In such an ovule the chalaza, ch, is at the base, and the micropyle, m, at the apex, and no curvature nor inversion takes place either in the nucleus or in its coverings. In a Campylotropous (καμπύλος, curved) or curved ovule, the chalaza is still at the hilum, but the whole ovule is bent upon itself, so that the micropyle or apex approaches the hilum. This is shown in Figure 294, which exhibits a vertical section of the ovule of Wallflower; the nucleus, n, is curved on itself, and so are the primine, p, and secundine, s; the chalaza, ch, is at

the base of the ovule, and the foramen or apex is close to it. In an Anatropous (dva- $\tau \rho \epsilon \pi \epsilon w$, to subvert) or inverted ovule (Fig. 295), an inversion of the nucleus, n, takes place, so that its base, ch, is removed to the opposite close to the hilum. In this case the chalaza, ch, is at the apparent apex of the ovule, and its connection with the placenta is kept up by a cord, r, called the

hive to the opposite side from the hilum, Fig. 294. Campylotropous or Campylotropal ovule of Wallfower (Cheiranthus), showing, f, the funiculus which attaches the ovule to the placenta, p the primine, s the secundine, n the nucleus, ch the chalaza. The ovule is curved upon itself, so that the foramen is near the funiculus.

295. Anatropous or Anatropal ovule of Dan-Anatropous or Anatropal ovule of Dam-delion (Leontodon Tranacoum), showing the coats of the ovule surrounding the nucleus, n, which is inverted, so that its base, ch, where the chalaza exists, is removed from the base or hilum of the ovule, h, while the foramen, f, is near the base. The connection between the base of the ovule and the base of the nucleus at s is kept up by means of the raphe, r.

Raphe, consisting of cellular tissue and of spiral vessels.

Botany. When the hilum is placed midway between the micropyle and the chalaza, the ovule becomes Heterotropal (ετέρος, diverse), and in such cases it frequently happens that the funiculus proceeds at right angles from the ovule, so that the latter becomes horizontal. Such ovules are considered by some as produced by a partial adhesion of the funiculus to the upper part of one side of the ovule.

Anatropous ovules are very common. They appear to be formed with the view of allowing the pollen tubes to reach the foramen easily. Campylotropous ovules are by no means uncommon. They are met with in Cruciferous and Caryophyllaceous plants, in Mignonette, and in the Bean. The orthotropous form is rare as a permanent condition of the ovule; it is met with in a few natural orders, such as the Buckwheat and Rock-rose tribes. Many look upon it as being the earliest state of all ovules, and refer the other forms to changes produced during growth.

Ovules vary in number. Sometimes there is a solitary ovule in each ovary, or in each loculament, at other times there are several. When the number is not great, and is uniform, the ovules are said to be definite, when very numerous they are indefinite. They are attached in various ways to the placenta, and their position in the ovary varies. When the placenta at the base of the ovary is the only part ovuliferous, then the ovule is erect, as in Polygonum. When the ovuliferous part is above the base, and the ovules proceed obliquely upwards, they are ascending, as in the Pellitory, and if they are developed equally on either side of the attachment, they are horizontal or peltate, as in Crassula. When the ovuliferous part of the placenta is at the apex of the ovary, the ovules are pendulous, as in Valerian, when below the apex, they are suspended, as in the Apricot (Fig. 275). In the Common Thrift, a funiculus extends from the placenta to the apex of the ovary, and curves downwards so as to suspend the ovule. When an ovary is multi-ovular (contains many ovules), the ovules may be all attached in the same way, and be placed either collaterally or one above the other (Fig. 279); or they may be attached in different ways, so that some are erect and others pendulous. These terms apply only to the position of the ovule as respects the ovary, and they have reference alike to orthotropous, campylotropous, and anatropous ovules. Thus, an anatropous ovule may be either erect or pendulous as regards its position in the ovary. The same terms apply to the seed in its relation to the seed-vessel.

Some ovules are not contained in a true pistil, i.e., in a

and stigma. These ovules are met with in the Cycas* and Cone-bearing orders. In the former, the ovules are arranged on the edges of metamorphosed leaves, and the pollen from the male flowers is applied directly to them, without the intervention of a stigma. In the latter

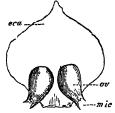

tion of a stigma. In the latter the ovules (Fig. 296, ov) are covered by scales, eca, which are hardened bracts or floral leaves covering the female flowers. In this case also the pollen is applied to the micropyle, mic, of the ovules, without the intervention of a stigma.

1. The latter Fig. 296. Is stillate flower of a Fir (Pinus), consisting of a scale, eca, which is a hardened bract, and two ovules, constituted to its base. The object of the ovules also the pollen is applied to the micropyle, mic, of the ovules, without the intervention of a stigma.

carpel consisting of true ovary

*Plate

CXXXIV.

†† Pistil after becoming the Fruit.

The Fruit-is, properly speaking, the pistil arrived at maturity, containing the ripe seeds, in which the embryo plant is developed (Fig. 297, pl). The simplest form of fruit is that formed by a single carpel, inclosing one or more seeds (Fig. 276). It often happens that changes take place

by which some parts of the carpel are rendered succu- Botany. lent, and, then, in place of a dry fruit, there is produced a fleshy one. This is well seen in the case of the Peach, in which the outer epidermal covering of the carpel forms what is called the skin, the parenchymatous cells of the mesophyllum constitute the flesh, and the inner epidermis of the carpellary leaf is changed into the stone; the kernel being the ripe seed containing the embryo plant. In the Coco-nut, in place of fleshy cells, woody fibrous ones are produced; the outer layer of the husk representing the external epidermis of the ovarian carpel, the fibrous portion being the parenchyma of the carpel, and the hard shell being the inner epidermis of the carpel inclosing the seed and the embryo.

As in the case of the pistil, so in the fruit, the carpels composing it may be distinct or united. When the fruit consists of a single ripe carpel, or of several separate and distinct carpels, it is said to be Apocarpous or Dialycarpous, as in the Pea (Fig. 276) where there is a single carpel, and in the Ranunculus (Fig. 277), and Columbine (Fig. 298),

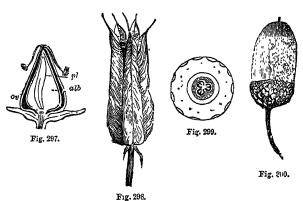

Fig. 298.

Fig. 297. Fruit of a species of Dock (Rumez), cut vertically. It is a monospermous indehiscent dry fruit, called an Achne, or Ackanium. The outer part, ov, is the pericarp or seed-vessel containing the seed, with its coverings. The seed contains nourishing mater, called albumen or perisperm, alp, and the embryo plant, pl, with its cotyledons pointing downwards, and its radicle upwards. The seed is orthotropal, and the embryo is inverted. At the upper part of the pericarp two of the styles and stigmas are seen curving downwards. At the base, part of the perianth is represented.

298. Apocarpous fruit of Columbine (Aquilegia vulgaris), consisting of five separate mature carpels, with styles and stigmas.

299. Transverse section of the Acorn (glans), showing the three carpels with two voules in each, of which it is originally composed. Two of the carpels and five of the ovules are obliterated during the progress of growth, so that the mature fruit is unifocular and monospermal. Surrounding the ovary the mass of bracts is seen.

300. Acorn, or fruit of the Oak (Quercus), consisting of the ovary containing a single seed, and surrounded by a series of bracts which form the cup or cupula.

in which there are several separate mature carpels. When the mature carpels are combined, as in the Poppy, the fruit is Syncarpous. Sometimes the mature pistils of several flowers are incorporated into one hard or succulent mass, as in the Cone, in the Mulberry, and in the Fig (Fig. 157), and in these instances, what is commonly called the fruit, consists, in reality, of a great number of fruits united together. Such fruits are called Collective or Multiple.

The fruit may be formed not merely by the pistil, but also by other parts of the flower united to it, more or less completely. Thus, in the Apple, Pear, Gooseberry, Currant, and Melon, the calyx is combined with the pistil; in the Hazel-nut, the Acorn (Fig. 300), and Chestnut, bracts form the husk, the cup, and the burr; in the Rose the receptacle is enlarged, and covers the pistil. Occasionally the fruit seems to consist not merely of a number of rows of transformed leaves, but of a transformed branch in addition.

By ascertaining the anatomy and structure of the pistil, we are led to a knowledge of the nature of the fruit, and we are enabled to see the changes which take place during growth. These changes depend on increase of the parenchyma, adhesion of one part to another, obliteration of lo-

Botany. culaments or of ovules, and the development of additional processes or partitions from the placenta, and from other parts of the pistil. Thus, the Coco-nut in its young state, is formed by three carpels, each containing a single ovule, while in its mature condition there is only one loculament and one seed. In this case the partitions between the carpels are obliterated, and one ovule is developed at the expense of the other two. These changes may be traced on careful examination; and even in the ripe fruit indications of them are seen in the markings on the shell. The Acorn in its early condition (Fig. 299), is formed of three carpels, with two ovules in each, as seen in the Figure, but in the progress of development changes are induced by which the fruit (Fig. 300) becomes one-celled and one-seeded. In these cases a trilocular sex-ovular pistil becomes a unilocular and monospermic fruit. In the Hazel, the Ash, the Elm, the Beech, and the Horse-chestnut, similar changes are produced in the pistil by the abortion of ovules, and the obliteration of divisions. In the Thorn-apple the pistil is formed of two carpels, separated by a septum, while the fruit exhibits four loculaments, produced by prolongations from the placentas, forming a spurious septum in each carpel.

It sometimes happens that the receptacle or peduncle becomes succulent, and is called the fruit in ordinary language.

Thus, in the Strawberry (Fig. 301), the true fruit consists of small single-seeded (monospermic) dry seed-vessels (commonly called seeds), scattered over a succulent convex receptacle; in the Rose, the true fruit consists of similar seed-vessels arranged on a fleshy concave receptacle (Fig. 185); and in the Fig the true fruit consists of monospermic seed-vessels produced by separate flowers, and scattered over the inner surface The fruit of the of a concave succulent receptacle (Fig. 157). *Pl.CXVI. In the Cashew,* the nut or true fruit is borne on a coloured succulent stalk, which enlarges during ripening.

In the interior of some fruits a pulpy substance is produced, apparently as a secretion from the inner lining of the ovary. This kind of pulpy matter is met with in the Gooseberry, Currant, Grape, Orange, and

The fruit of the Strawberry (Fragaria vesca) consisting of the enlarged succulent receptacle, or growing point, bearing on its surface numerous single-seeded carpels or achenes. Each achene has a style and stigma, and is thus at once distinguished from a seed. pod of Cassia Fistula. Occasionally the organs adjacent to the pistil become the succulent parts of the fruit. In Strawberry-Blite, the calyx surrounding the pistil, and separate from it, becomes red and juicy; in Gualtheria procumbens, the free calyx, after flowering, becomes red and succulent, surrounding the true fruit, which is dry. In the Yew, the bracts enveloping the seed become succulent.

The fruit, generally speaking, consists of the seed-vessel or Pericarp ($\pi\epsilon\rho$), $m\epsilon$ around, and $\kappa \alpha \rho \pi \delta s$, fruit), and the Seed. en It cannot be said to be perfect unless the seed and embryo are produced. In many cultivated fruits, however, the seeds are abortive. Thus, in the case of the Bread-fruit, Banana, and Pine-apple, the best fruit is seedless, and such is often true of the Orange and the Grape. The Drupe of the Cherry (Corasus), out vertically the carpellary leaf, and, like it, can be separated into three parts; the outer epidermal covering (Fig. 302, ep), called Epicarp, or Exocarp. (en), upon, etc. Epicarp, or Exocarp, (ἐπὶ, upon, ἔξω,

Fig. 302.

Fig. 301.

outside, καρποs, fruit); the middle parenchymatous portion, me, called Mesocarp (µέσος, middle), and when succulent, Sarcocarp (σὰρξ, flesh), and the inner epidermal covering, en, called Endocarp (& Soo, within), and when hard and stony Putamen (putamen, the shell of a nut). These

three coverings are well seen in the Peach, in the Cherry, and in the Date. In their original structure these parts correspond with the leaf, but changes take place during ripening, by which some cells are hardened and others become succulent, and thus the resemblance to the leaf is much obscured. That succulent fruits, such as the Peach, Apricot, and Cherry, are to be regarded as altered carpellary leaves, is shown in the case of the double Cherry, where true leaves occupy the place of the fruit (Fig. 186). Dr Wyville Thomson records instances of the common Sloe and Bird-cherry producing red-coloured follicular pods. In many fruits, as in the Nut, the different pericarpial layers are so blended that it is not easy to mark their separation.

Some fruits fall without opening or dehiscing, the seeds being liberated during the process of decay; such fruits are Indehiscent (indehisco, not to open). Other fruits open or dehisce in various ways, so as to scatter the seeds, and are called Dehiscent. The dehiscence takes place either in a vertical or in a transverse direction; the former is the usual mode. Vertical dehiscence takes place through the sutures, or by the separation of the parts of which a syncarpous fruit is composed. The separate parts are called Valves. In fruits formed by a single carpel, the dehiscence occurs either at the ventral or dorsal suture, or both. In the follicles of the Pæony, the Columbine (Fig. 298), and the Marsh Marigold, the dehiscence is ventral; in Magnolia grandiflora the dehiscence is sometimes dorsal; while in the pod of the Pea (Fig. 276) and of the Bean, it is both ventral and dorsal.

When the fruit consists of several carpels united, or is syncarpous, the dehiscence takes place either by a separation of the constituent carpels through the dissepiments (Fig. 303), and in that case is Septicidal (septum, partition,

Fig. 303. Diagram to illustrate the septicidal dehiscence in a pentalocular capsule. The loculaments, L correspond to the number of the carpels, which separate by splitting through the septa, s.

304. Diagram to illustrate loculicidal dehiscence. The loculaments, L, split at the back, and the valves separate, bearing the septa, s, in their centres.

305. Diagram to illustrate septifragal dehiscence, in which the dehiscence takes place through the back of the loculaments, L, and the valves separate from the septa, s, which are left attached to the placentas in the centre.

and cædo, to cut), as in Figwort and Gentian, where there are two valves, in Meadow-saffron, where there are three valves, and in the Fig-Marigold and the Rhododendron, where there are five or more valves; or the dehiscence takes place by the dorsal suture of each carpel (Fig. 304), and in that case is Loculicidal (loculus, a loculament, and cædo, to cut), as in the Iris, the Pansy, the Lily, and the Horse-chestnut.

There are modifications of these kinds of dehiscence. Thus, in the septicidal form the valves, on separating, sometimes carry the placentas with them, as in Gentian and Colchicum (Fig. 287); at other times, the placentas or placentaries are left attached to the central axis or columella, as in Rhododendron. In the case of Hura, Euphorbia, and Janipha,* each carpel, or coccus as it is called, separates *Pl. CXIII. from the columella, carrying with it an inclosed seed. In fig. 2. the loculicidal dehiscence the dissepiments may remain attached to the middle of each of the valves, and separate along with them, or the septa may adhere to the axis, and allow the valves to fall off without them (Fig. 305), as in the Thorn-apple and Purple Convolvulus. The latter kind of loculicidal dehiscence is called Septifragal (septum, a partition, and frango, to break). In some cases the dehiscence is at first loculicidal, and afterwards the carpels separate

fig. 1.

Botany. from each other in a septicidal manner. This union of the two kinds of dehiscence is seen in some Spurges, in the *Pl. CXV. Castor-oil fruit, and in the Purging Flax.*

In Orchis, the placentas, as represented in Figure 282, are parietal, and the seed-vessel opens by three valves (Fig. 306, v), which are placentiferous in their middle, but

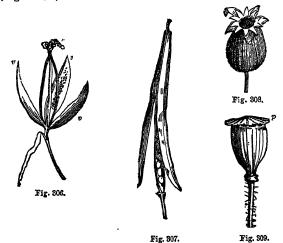

Fig. 306. Seed-vessel of an Orchid (Orchis), opening by three valves, v v v, which bear the placentas and seeds in their middle. The midros of the carpels remain united at the base and apex, and the withered fioral envelopes, e, are seen attached at the apex.

307. Siliqua or seed-vessel of Wallidower (Oheiranthus Cheiri), opening by two valves, which separate from the base upwards, leaving the seeds attached to the placentas in the middle, with a replum

seeus attached to the parameters, opening by ten teeth at the apex. The placents is free central. The calyx is seen surrounding the seed-vessel, but not adherent.

309. Capsule of Poppy (Papaver), opening by pores, p, under the broad peltate stigma.

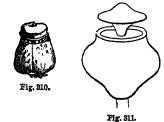

the midribs of the three carpels remain united at their base and summit, and the withered floral envelopes, e, are seen attached at the apex. In the pod of cruciferous plants, such as Wallflower, Whitlow-grass, and Shepherd's-purse, as well as in the pod-like fruit of Celandine, two valves separate from the base upwards (Fig. 307), leaving the parietal placentas united together by a cellular frame or replum, which is either entire or perforated. In vertical dehiscence the splitting sometimes takes place only at the apex of the fruit, so that the seed-vessel opens by teeth, as in Campion (Fig. 308), and Mouse-ear Chickweed, or by pores, as in the *PI. CXII. Poppy* (Fig. 309), or by rupturing, as in Frogsmouth, or by one large orifice, as in Mignonette. In the Bell-flower, the seed-vessel dehisces in a loculicidal manner laterally, or near the base.

Transverse dehiscence is of rare occurrence. It is seen

*Plate JIIVXXC

fig. 2.

in Henbane* (Fig. 310), Pimpernel, Purslane, and in various species of Monkey-pot (Fig. 311), in which the upper part of the fruit separates like a lid. This is called Circumscissile (circum, around, and scissilis, cleft) deleaves which separate at the articulationsthe united petioles forming the lower part of

hiscence, and seems to Fig. 310. Seed-vessel of Henbane (Hyoscyamus indicate that the seed-vessel in these cases is formed by jointed

The dehiscence is transverse or circumscissile, and the capsule is operculate or lidded.

the fruit, and the united laminæ constituting the lid. Carpology.—A classification of fruits ought properly to

be founded on a consideration of their original formation, Botany. and of their anatomical structure in the early state. This is often puzzling to the student, inasmuch as it requires that he should trace the fruit during its different stages of development. By so doing, however, he is enabled to observe the various changes which take place by absorption, obliteration, adhesion, and division of parts, and he is in a condition to explain many apparent anomalies. Thus, in the Coco-nut, he sees that there are at first three loculaments and three ovules, but as the fruit ripens, two of each of them disappear, and finally only one remains. The three ridges, however, which remain on the endocarp, are at once explained by a reference to the early condition of the nut. Such is the case with many fruits, the structure of which would be obscure without a knowledge of the morphological alterations which have taken place. The names applied to fruits have a reference chiefly to their fully developed

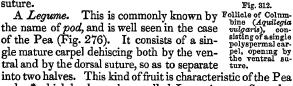

Without attempting to give a rigorous and minute definition of Carpological (καρπός, fruit, and λόγος, discourse) terms which have been multiplied to a cumbrous extent, we shall merely explain some of those which are most frequently employed, arranging them according as they refer to fruits formed by a single separate flower, and which are called Simple or Monogynacial (formed by one Gynacium); or to fruits formed by a combination of numerous flowers, and which are called Collective, Multiple, Anthocarpous $(a\nu\theta os, flower, and \kappa a\rho\pi os, fruit), or Polygynæcial (formed)$ by many Gynœcia).

Simple or Monogynæcial Fruits.—These may consist either of a single mature carpel, or of numerous separate carpels, arranged in one or more rows in a circular manner, on flat convex or concave receptacles. They may be formed not only of the pistil but of the other parts of the flower united to it, and they may either be dehiscent or indehiscent, dry or succulent.

A Follicle is a fruit formed by a single mature carpel de-

hiscing by the ventral suture (Fig. 312). The fruit may consist of a single follicle, as is seen occasionally in the Pæony; more commonly it is formed by two or more separate follicles arranged in a circular or spiral manner, as in the Marsh Marigold, and Columbine (Fig. 298). In some follicular fruits the opening takes place by the dorsal

the name of pod, and is well seen in the case of the Pea (Fig. 276). It consists of a single mature carpel dehiscing both by the ventral and by the dorsal suture, so as to separate

order,* which has hence been called Leguminous. Some le- * Plate gumes, as those of Cathartocarpus Fistula, do not open; others CXVIL have divisions between each of the seeds formed by transverse foldings, as in Sainfoin (Fig. 313), and Bird's-foot. The latter is called a lomentaceous or moniliform legume or a Lomentum, and when mature it usually separates into pieces, each of which contains a single seed. In some legumes, a spurious division is formed in a vertical manner by a prolongation from the placenta, or by a folding inwards of the dorsal suture. The legume is sometimes twisted, and spiral; at other times it has a leafy and inflated aspect, as in Bladder-Senna. In some legumes, the outer portion or the exocarp (epicarp) separates from the endocarp, which still remains covering the seeds. In some indehiscent monospermal legumes the coverings become succulent; so that they are really drupaceous, thus establishing a connection between the Leguminous and Rosaceous orders.

A Siliqua is another kind of pod, formed (according to most authors) by the union of two carpellary leaves with

Botany. parietal placentas, and dehiscing by two valves which separate from below upwards. It is well seen in the common Wallflower (Fig. 307), and in other Cruciferous plants. The two valves separate from the placentas, leaving them united

> Fig. 313. Fig. 316.

> > Fig. 314.

Fig. 313. Lomentum or lomentaceous legume of a species of Sainfoin (Hedysarum). Each seed is contained in a separate cavity by the folding inwards of the walls of the legume at equal intervals; and the legume, when ripe, separates transversely into single seeded portions.

314. Compound ovary (Siliqua) of Waliflower (Cheiranthus), consisting of at least two carpels united. One valve has been removed to show the partition or replum, ci, formed of a double layer from the placents, cn, on either side, to which the ovules ou, are attached by means of funiculi. The style and stigma, s, are at the upper part of the ovary.

the ovary.

315. Silicula of Whitlow-grass (Draba), opening by two flat valves, o, from below upwards, leaving the parietal placentas, pl, in the centre, united by a membrane or replum. The partition of the seedvessel is broad, and hence the name Latiseptæ.

316. Silicula or pouch of Shepherd's-purse (Capsella), opening by two folded valves, which separate from below upwards. The Phragma

is narrow (angustiseptæ).

by a cellular prolongation or replum (Fig. 314, cl), which divides the seed-vessel vertically into two loculaments. A broad and short siliqua has received the name of Silicula. In it (the silicle) the carpellary leaves are either united together, so that the septum is in the broadest diameter of the pod (latiseptæ), as in Thlaspi and Draba (Fig. 315); or the carpels are folded so that their dorsal suture is prominent, and the replum is narrow or linear (angustiseptæ), as in the Shepherd's-purse (Fig. 316). The Siliqua and Silicula are occasionally indehiscent and monospermal (μόνος, one, σπέρμα, a seed).

A Capsule is a dry syncarpous fruit dehiscing either vertically by valves, teeth, or pores, or transversely by a lid. It is composed of several carpels united, and it may exhibit all the kinds of dehiscence to which reference has already been made. In Caryophyllaceous plants, the dehiscence of the capsule often takes place by short valvular teeth (Fig. 308), in the Mahogany fruit by complete valves which separate from below upwards, in Colchicum and in Cotton, by valves separating from above downwards, in the Poppy (Fig. 309) by pores below the stigma, in Frogsmouth by rupturing at the apex, in Mignonette by becoming patent at the apex, in Campanula by irregular openings near the base, in Henbane (Fig. 310) by a lid, in which case the capsule sometimes receives the name of pyxidium, in Spurges* by the sudden separation of elastic cocci or carpels, each containing one seed, and in the Balsam by the separation of five elastic valves which coil upwards.

An Achænium or Achene (a, priv., and xaíveu to open) is a dry indehiscent one-seeded (monospermous) fruit, as in Crowfoot (Fig. 317). It is formed of a single carpel which VOL. V.

is closely applied to the seed. At first sight it is difficult Botany. to distinguish this kind of seed-vessel from a seed, and hence Linnæus termed some achene-bearing plants naked-seeded (gymnospermia—γυμνος, naked, σπέρ- μa , a seed). It is common to find several separate achenes forming the fruit. In Buttercups, the achenes are aggregated on a convex receptacle (Fig. 277), in the Strawberry they are placed on a convex succulent receptacle (Fig. 301), and in the Rose on a concave receptacle (Fig. 185). In all these cases, the presence of styles and stigmata enables the student to ascertain that what are commonly called seeds are in reality fruits. In the

Fig. 317. Achenium of Crowfoot (Ranunculus). A single-seeded seed vessel, with the peri-carp applied closely to the seed. Such fruits resemble seeds in appearance; the style and stigma, s, aid in distinguishing them.

instances already noticed, the numerous achenes are the produce of a single flower, but cases occur, such as the Fig (Fig. 157) and Dorstenia (Fig. 156), in which they are each the produce of a separate flower. In the Borage and Mint orders, the two or four achenes forming the ripe fruit (Fig. 318) are at first united, and even when matured, there is a common style which is attached to the apparent base of each achene. Cases also occur in which the achænia are united to the tube of the calvx.

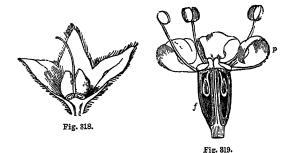

Fig. 318, Calyx and fruit of Comfrey (Symphytum), cut vertically. The fruit is divided by the folding of the overy into four single-seeded portions or achema, two of which are seen in the figure, and the style appears to arise from the base of the carpels.

319. Flower of Fenuel (Fomiculum vulgare), one of the Umbelliferse, cut vertically, showing the fruit, f, composed of two single-seeded carpels, or achenes, united, so as to form a cremocarp. The pendulous seeds are seen in the carpels or mericarps. The two styles are seen at the apex of the fruit, with their dilated bases formed by an epignnous disk. The points (apicula) of the petals, p, are turned inwards. The calyx tube is adherent to the fruit, and the limb of the calyx is often obsolete.

Thus in Composite plants, such as the Thistle and Dandelion, what are called seeds are in reality single-seeded fruits, each produced by a separate flower, with the tube of the calyx united to it, and the limb of the calyx appearing as a rim or as a hairy appendage, called pappus (Figs. 206 and 252).

In Umbel-bearing plants, such as Hemlock and Fennel, two achænia, invested by the tube of the calyx, are united by their faces, so as to form a compound fruit called a Cremocarp* (κρέμαεν, to suspend, and καρπὸς fruit), with a division or commissure between them (Fig. 319). This fruit, when ripe, shows its composition by separating into two achenes (called here, mericarps or hemicarps, μέρος, part, ημισυς half), which are suspended by a slender central stalk or axis (Fig. 320), called a Carpophore (καρπὸς, fruit, and φορέειν, to bear). The outer surface of these mericarps is marked by ridges and furrows, and there are often peculiar vittæ or receptacles of oil present in the peri-

Botany.

dehiscent monospermous seed-vessel resembling an achæ-

nium, but differing in the complete adhesion and incorporation which exists between the pericarpial covering and the seed. It is seen in the common cultivated grains, as Wheat and Oats (Fig. 321), and in general in all Grasses. In these plants the pericarp cannot be separated from the seed. Hence the grains of Wheat, Maize, Barley, Rye, and Oats, are in common language called seeds. It is only by examining them in the early state, and noticing the styles, that we can determine their real nature.

A Nut is a dry unilocular one-seeded indehiscent fruit with a hard covering. In its early state, it is usually composed of two or more carpels, with one or more ovules in each; but, in the progress of growth, all disappear except one. It is illustrated by the Hazel-nut, the Chestnut, the Acorn (Fig. 300), and the Coco-nut. In many cases it is surrounded by a series

of bracts forming an involucre, seen in the root, r. the husk of the Nut, the cup of the Acorn, and the burr of the Chestnut. Some restrict the term nut (glans) entirely to such cases. The pericarp of the nut has its parts frequently so united as not to be distinguished from each other. In the Coco-nut, however, the pericarp can be separated into an epicarp or outer covering, a fibrous mesocarp, and a stony endocarp, marked with three ridges and three depressions, one of which is perforated. The epicarp of the nut of the Sago-Palm is scaly.

A Samara (Samera, seed of Elm), is a nut or achænium,

in which the pericarp is extended in the form of a winged margin or apex. There are originally two carpels united, but one of them is frequently abortive. This samaroid fruit occurs in the Maple (Fig. 322), and Sycamore, the Ash, and the Elm. The samara of the Sycamore opens by splitting into two in a septicidal manner.

A Drupe is the general name given to what are called stone-fruits, such as the Peach, the Plum, the Cherry, the Apricot, the Date, the Olive, and Coffee. It is a one-

Fig. 822. Branch of the Sugar-Maple (Acer saccharinum), bearing a cluster of samaroid fruit.

celled, one or two-seeded indehiscent fruit, having a fleshy mesocarp, which is hence denominated sarcocarp. In the Peach, the epicarp is the separable skin, the sarcocarp is the flesh which is eaten, and the endocarp is the hard shell or putamen, which can be split into two parts. In the Walnut, the putamen is divided in a marked manner into two, and from its interior bony partitions extend, so as to form lobes in the seed or kernel. Some fruits, such as the Almond, are called drupes or drupaceous, in which the sarcocarp is not succulent. Many call the Coco-nut a drupe, with a fibrous mesocarp. There seems to be, in reality, in such cases, a transition from the drupe to the nut. The aggregation of several drupes forms the fruit of the Raspberry, the Bramble, and the Quassia plant.

A Berry or Bacca, is the name given to all indehiscent syncarpous fruits, the seeds of which are immersed in a pulpy or fleshy mass. Such fruits are collectively called baccate or berried. In the true berry, such as the Gooseberry and Currant, the calyx adheres to the fruit, and the placentas are parietal (Fig. 323), while in the grape (Uva) the ovary alone is present, Botany. and the placentas are central. Instances

of baccate fruits are seen in Solanaceous plants,* such as the Potato, Belladonna,* Winter Cherry, (Fig. 207) and Mistleto.

In the Pomegranate there is a peculiar succulent berried fruit, called a Balausta (balaustium, the flower of the Pomegranate), in which the pulpy cells are arranged in two rows, some of which are in the centre round the axis, and others are placed outside, all being adherent to the calyx. In the Orange there is a modification of the berry, called Hesperidizm (the golden fruit in the garden of the Hesperides) in which there is a separable wind not formed by the cells. The fruit is called a Bacca.

rind not formed by the calyx, consisting of epicarp and mesocarp, and pulpy separable cells formed by the endocarp.

Cucumber and Melon (Fig. 324). It consists of three carpels united, covered by a firm rind, which is partly formed by the calyx. The placentas are by some considered as parietal, and as sending processes inwards, by others p they are looked upon as central, and as sending processes outwards, which reach the walls of the fruit and then curve backwards, bearing the seeds. The processes proceeding from the axis to the walls are usually obliterated, according to the latter view, giving rise to the appearance of the placentas being parietal. The fruit thus becomes one-celled. A transverse section of the Melon

From the centre, processes, s, go to the circumsterence, t, ending in enred placentaries bearing the ovules. These placentas by some are considered as parietal, formed on the walls of the truit, by others they are looked upon as the curved terminations of the contral processes, s.

Fig. 324.

is given in Fig. 324, in which pl indicates the placentas, cl the septa, and s the processes connecting the curved placentas with the centre. In the Plantain and Banana, the fruit is allied to the pepo, consisting of three carpels, with parietal placentas, the perianth being adherent to the ovary, and the seeds immersed in a pulpy mass when ripe.

A Pome is a fleshy syncarpous fruit composed of two or more scaly, or horny, or bony carpels, covered by a pulpy mass, which is incorporated with the calvx. fleshy portion may be considered either as the combined epicarp and mesocarp, or it may be reckoned the receptacle enlarged, as in the Rose, and united to the calyx. This

kind of fruit is seen in the Apple (Fig. 325), the Pear, the Quince, and the Medlar. The cartilaginous cells inclosing the seeds of the Apple, and the bony coverings (nucleus) of the seeds of the Medlar, may be reckoned either as the endocarp, or as the entire pericarp, according to the view taken of the formation of the pulpy exterior.

Multiple, Collective or Polygynæcial Fruits.—These fruits are formed by the Gynœcia of several flowers united, and the name anthocarpous is also applied, because they consist usually of the bracts and floral envelopes combined with the ovaries. They are either indehiscent or dehiscent, succulent or drv.

Fig. 325. Section of the fruit of ection of the fruit of the Apple (Pyrus Malus), consisting of a fleshy covering partly formed by the calyx, and five cavities in the centre with seeds. The fruit is called a Pome. In the Medlar the endocarp is stony.

The seedless of the seedless of the seedless.

Botany.

A Cone, Strobilus (στρόβιλος, a fir-cone), is a form of collective fruit, composed of scales or bracts covering one or more naked seeds (Fig. 296). Some consider these scales as carpels spread out, but from the absence of style and stigma, they seem more properly referable to floral leaves or bracts. The cone gives name to the natural order Coniferæ, or Cone-bearers, such as the Fir and Larch. In the Juniper the scales of the cone are succulent, and the fruit has sometimes received the name of Galbulus. In the Yew the bracts enveloping the naked seed also become succulent.

In the Fig (Fig. 157) a multiple fruit occurs, called Syconus (σῦκον, a fig), consisting of numerons flowers inclosed in a hollow receptale. What are called the seeds of the Fig, are in reality monospermous seed-vessels (achenes), with styles and stigmata. In the Mulberry, Bread-fruit

(Fig. 326), and Pine-apple, the ovaries and floral envelopes of several flowers are all united into one fleshy mass, placed on a more or less convex or elongated receptacle, and the fruit is called a Sorosis (σωρὸς, a congeries or cluster). The crown of the Pine-apple may be regarded as a series of empty bracts terminating the axis. In the strobili of the Hop, the bracts covering the flowers are membranous in place of being succulent.

Transformations in Fruits.—The same causes which produce alterations in the other parts of the flower, give rise to anomalous appearances in the The carpels, in place of bearing seeds, are sometimes changed into leaves, with lobes at their margin.

male flowers, a, are arranged in a spike. Leaves are sometimes produced from the upper part of the fruit, which is then called frondiparous, (frons, a leaf, and pario, to produce). In the genus Citrus, to which the Orange and Lemon belong, it is very common to meet with a separation of the carpels, so as to produce what are called horned oranges and fingered citrons. In this case a syncarpous fruit has a tendency to become apocarpous. Orange we occasionally find a supernumerary row of carpels produced, giving rise to the appearance of small and imperfect oranges inclosed within the original one. sometimes happens that, by the union of flowers, double fruits are produced. Occasionally, a double fruit is produced, not by the incorporation of two flowers, but by the abnormal development of a second carpel in the flower.

The Seed.—When the ovule arrives at maturity it constitutes the seed, which is contained in a seed-vessel in the plants which are called Angiospermous (ayyos, a vessel, and $\sigma\pi$ έρμα, a seed); while, in *Gymnosperms* (γυμνὸς, naked, and σπέρμα, a seed), such as Coniferæ and Cycadaceæ, it is naked, or, in other words, has no true pericarpial covering. By far the larger number of flowering plants belong to the former division. It sometimes happens in Angiosperms, that the seed-vessel is ruptured at an early period of growth, so that the seeds become more or less fully exposed during their development; this occurs in Mignonette, where the capsule opens at the apex, and in Cuphea, where the placenta bursts through the ovary and floral envelopes, and appears as an erect process bearing the young seeds.

The seed (Fig. 327) consists of a nucleus, c, usually covered by two cellular integuments, e, and te, which are sometimes included under the general name of Spermoderm (σπέρμα, a seed, and δέρμα, skin). The outer integument is denominated the *Episperm*, *Exosperm*, or more commonly the Testa (Fig 327, te). It corresponds usually to the primine of the ovule, but it is frequently formed by a union of both primine and secundine. It varies in its texture, being metimes thin and membranaceous, at other times thick and

hard. It presents various colours, being brown, white, red, black, and mottled. Its surface sometimes presents ridges and furrows, as in Larkspur, reticulations, as in the Water

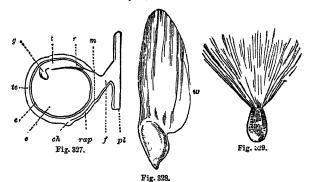

Fig. 327. The seed of the Pea (Pisum), deprived of one-half of its integrment or spermoderm. The outer covering called either epicarp, exocarp, or testa, is marked te, the inner, called endocarp, e. Within these integrments is the nucleus, consisting of cotyledons or seed-lobes, o, containing nourshing matter the gemmule, or young leaf-bud, q, the radicle, or young root, r, the tigelle or stalk between root and bud, t. The seed is attached to the placenta, pl. by a cord or funioulus, f. The nourshing vessels, rap, enter the nucleus at the chalza, ch, and the root of the embryo points to the micropyle or foramen, m.

238. Seed of Fir (Pinus), with a membranous appendage, w, to the testa, called a wing: The seed is said to be winged.

329. Seed of Far (Pinus), with a cluster of hairs arising from the edges of the micropyle, and by some considered as a hairy aril. These hairs are for the purpose of scattering the seed.

Cress, alveolar depressions, as in the Poppy, and tubercular eminences, as in Chickweed. Occasionally, the seminal integument is furnished with appendages in the form of wings, as in Pine seeds (Fig. 328) and Bignonia, or with a margin as in Sandwort; and at other times it is provided with hairs, as in the Cotton plant, Asclepias (Fig. 329), and the Willow. It is of importance to distinguish between such hairs and the pappus of Composite plants, and of Valerian,* which is in *Plate reality an abortive calycine limb attached to the fruit. We CXXII. have already stated that the presence of the style or stigma fig. 3. distinguishes single-seeded fruits from seeds.

The seed of some Polemoniaceous plants has a covering, consisting of small cells or hairs containing spiral fibres inside. These hairs are closely applied to the surface of the episperm, and are confined by a mucilaginous coating. When placed in water, the mucilage dissolves, and the hairs are liberated, so as to spread out in all directions. The walls of the cells are also usually ruptured, so as to allow the spiral fibres to uncoil, and form a beautiful object under the microscope. The same kind of structure occurs in the pericarpial covering of some Labiate plants, such as Salvia, and of some Composite plants, such as Senecio. The spreading out of these fibrous cells is apparently intended for the purpose of fixing the seed in the moist soil, into which they are carried by the wind. Sometimes the secundine of the ovule assumes a succulent consistence in the seed, and

The Endopleura or Tegmen is the inner seminal envelope or integument. In general, it is formed from the tercine or the membrane of the nucleus, and it is sometimes united with the embryo-sac. In some cases, as in the Water-Lily, Ginger, and Pepper, this sac remains as a distinct covering of the young plant under the name of the vitellus (Fig. 333, es). The endopleura is often incorporated with the testa, and scarcely separable from it. It is composed usually of a thin layer of cellular tissue, and when the nucleus is sinuous, as in the Walnut, it follows its windings, so as to enter between the lobes.

forms a lining to the episperm.

The spermoderm, or general seminal integument, has certain markings corresponding to those mentioned in the ovule. Thus, we observe the micropyle or small opening in the coats which extends to the nucleus (Fig. 327, m), the chalaza (Fig. 327, ch) or the fibro-vascular connection between the nucleus and the coats, and the base or hilum by

Botany. which the seed is connected with the funiculus (Fig. 327, f). These parts bear the same relation to each other as they do in the ovule. Thus, in an orthotropous seed, the hilum and chalaza are united, and the micropyle is at the opposite end or apex; in a campylotropous seed, the hilum and chalaza are united, and the micropyle is slightly removed from the hilum; while in an anatropous seed, the nucleus is invertedits base and the chalaza being removed from the hilum, and the micropyle being close to the hilum.

The micropyle is smaller and less distinct in the fullgrown seed than it was in the ovule. It indicates the place where the radicular extremity of the embryo is situated. Its situation in the Bean and Pea, when they begin to sprout, is marked by a little lid-like process (embryotega) which is pushed upwards. The chalaza is more or less evident in different seeds. It is conspicuous in anatropous seeds, such as the Orange (Fig. 330, c), where the raphe (Fig. 331, r) or vascular connection between it and the placenta exists. The raphe forms a cord usually along the inner side of the

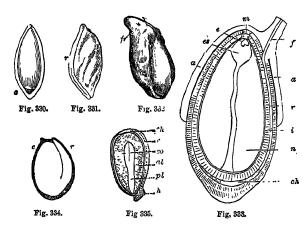

Fig. 334. Fig 335. Fig, 333.

331. Entire anatropal seed of the Orange (Citrus), with its rucose or wrinkled te-ta, and the raphe or internal funiculus, r, ramifying in the thickness of the tests on one side.
332. Arillode, a, the false aril of the Spindle-tree (Euonymus), arising from the micropyle, f.
333. Arillode, a, the false aril of the Spindle-tree (Euonymus), arising from the micropyle, f.
334. Young anatropal seed of the White Water-Lily Nymphæa alba), cut vertically. It is attached to the placenta by the funiculus or umbilical cord, f, cellular prolongations from which form an aril, a. The vessels of the cord are prolonged to the base of the nucleus, n, by means of the raphe, r, composed of cells and spiral ressels. The base of the nucleus is indicated by the chalaza, ch, while the apex is at the micropyle, m. The covering of the seed is marked t. The nucleus, n, is composed of albumen or perisperm, surrounded by its covering, and inclosing the embryo-sac, es, which remains in the rips seed in the form of a vitellus. The embryo e, with its suspensor, is contained in the sac, the radicle pointing to the micropyle m.
334. Seed of Wallflower (Cheiranthus) out vertically. The seed is exalbuminous or aperispermie—all the nourishing matter being incorporated with the cotyledons, c. On removing the integument which is marked by the dark lines, c. On removing the integument which is marked by the dark lines, the embryo alone is found in the interior. The radicle, r, is folded on the edges of the cotyledons, which are accumbent; the plant belongs to the division of oracifers, called Pleuronizee.
335. The seed of the Pansy (Viola tricolor) cut vertically. The seed is anatropal, and the embryo is orthotropal, the cotyledons, co, point to the base of the nucleus or chalaza, ch, while the the radicle, or the other extre

seed, and may be considered as a prolongation from the funiculus, along with a covering derived from the integument of the seed. The scar or hilum is of different sizes and colours, and indicates the base of the seed or the place where it is attached to the placenta. This attachment is either direct, or is accomplished by the intervention of a stalk or cord called the funculus, which in Magnolias becomes much elongated. In the Bean the scar is of a black colour; in other cases it is white or brown. It sometimes extends over a large portion of the seed, as in the Horse-chestnut.

On the outside of the integument of the seed there is sometimes an additional partial covering of a cellular nature which is developed after the ovule is fertilized, and which

has received the name of Aril (arillus). It proceeds from Botany. the placenta or top of the funiculus in some instances, while in others it arises from the foramen of the seed. In the former case it is called a true or funicular aril, while in the latter it is called a false or micropylar aril, or sometimes Arillode. In the Passion-flower and Water-Lily, a funicular aril exists, while in the Spindle-tree, Nutmeg, Spurge, and Milkwort, a micropylar aril (Fig. 332, a) is seen. In the Nutmeg,* the arillode is laciniated and of a fine scarlet colour, *Plate constituting the mace. Certain cellular processes are occa-CXXXI. sionally seen at the base, apex, or sides of the seed, which fig. 6. have received the names of Caruncles and Strophioles.

The different parts of a seed are represented in Figure 333, n being the nucleus or central portion, composed of nourishing matter inclosing the embryo-sac, es, with the embryo-plant, e, the radicle of which points to the micropyle, m; f the funiculus, ch the chalaza, r the vessels running from the placenta to the base of the nucleus, i the integuments or spermoderm, and a a the funicular aril.

The nucleus or kernel of the seed (Fig. 333, n) is the fully-developed central portion of the ovule. It is much altered in general by the deposition of starchy, azotized, and ligneous matter, and by the development of the embryo. It consists either of the embryo alone, as in Wallflower (Fig. 334), or of the embryo along with a separate deposit of nourishing matter called the Albumen or Perisperm, as in the Pansy (Fig. 335). This albumen consists of starchy, ligneous, oily, saline, and nitrogenous substances contained in cells of various consistence. It is, therefore, not merely what chemists call vegetable albumen; and hence it is better to give it the name of perisperm or endosperm.

A seed is said to be albuminous or perispermic when it has a separate store of albumen distinct from the embryo, as in the Coco-nut, Wheat, and Pansy (Fig. 335); and exalbuminous or aperispermic when the nutritious matter is incorporated with the lobes of the embryo, as in Cruciferous plants (Fig. 334), in the Bean, the Pea (Fig. 327), and Almond. The perisperm varies in its consistence according to the nature of the deposit and the state of the cells. In the Vegetable-Ivory Palm, the cells are thickened by ligneous deposits, and the perisperm is of a horny consistence; so also in Coffee. In the Cereal grains, as Wheat, it is mealy and farinaceous; in the Poppy it is oily; in the Coco-nut it is cartilaginous; in the Mallow, mucilaginous. When cut, the perisperm may present a uniform appearance, as in Castor-Oil, or it may have a mottled or ruminated appearance, as in the Nutmeg* and Betel-nut. The latter *Plate depends on some unaltered cells of the endopleura or of the CXXXI. embryo-sac ramifying through the substance and forming fig. 11. convolutions. The proportion which the perisperm bears to the embryo varies much. Sometimes, as in the Coconut, in the Date, and in Monkshood, the embryo is very small, while the albumen is abundant; at other times, as in the Nettle, the embryo is large and the albumen small. The deposit of albumen takes place within the integuments of the seed. It either occupies the space between the endopleura and the embryo-sac, when it is called exospermic, as in the Water-Lily and other plants which have a distinct vitellus; or it is deposited within the sac, and then is endospermic; or it occupies both positions at once, and then may be called by the general name of perisperm.

The Embryo-is the young plant contained in the seed. It is the part to the production and nourishment of which all the floral organs contribute. It is contained originally in a cavity called the embryo-sac (Fig. 333, es), and appears at first as a small vesicle or cell (Fig. 333, e), attached to the sac by a cellular process called a suspensor, which is often very long, as in Cruciferous plants. The embryo-sac is sometimes separated from the endopleura by a quantity of perisperm (Fig. 333, n), at other times it is incorporated with it. The embryo-sac exhibits peculiar tubular prolon-

*Plate

CXXVI. fig. 5.

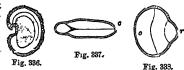

gations from its base and apex in some instances, as in the

Eyebright.

The Embryo in its structure exhibits cells and spiral vessels. It consists of a general axis, one part of which is concerned in the production of the root (Fig. 335, pl), and another in the formation of the stem (Fig. 335, co). The radical or root-portion of the axis always points to the micropyle of the seed. Hence, in orthotropal seeds, the embryo is said to be inverted, because its radicle points to the apex of the seed where the micropyle is situated, while in anatropal seeds (Fig. 335) it is erect. The axial portion of the embryo is provided with foliaceous or fleshy organs called seed-leaves (Fig. 335, co) or Cotyledons (κοτυληδών, name of a plant with fleshy leaves), which serve a temporary purpose in nutrition. From the upper part of the axis, the stem called the *Plumule* rises, bearing the ordinary, or *primordial* leaves of the plant. These separate parts are well seen when the young plant has begun to grow, as in Figure 59, where t is the general axis, with the roots, r, at the base, the cotyledons, cc, above, and the plumule with the primordial leaves, q q, coming from between the cotyledons.

The embryo is sometimes placed in the centre of the albumen, or in the axis of the seed, and in a straight direction (Fig. 335), it is then axile or axial; when not in the centre of the seed it is abaxile or eccentric. In place of being straight it is often curved in various ways. This may depend on the curvature of the seed itself, as in the Snake-nut, and in Campylotropous seeds; or the seed may be straight, and the embryo alone curved. In the Chickweed order the embryo is curved round the albumen (Fig. 336), becoming peripherical. In other cases, as the Thorn-

apple and Solanum,*it is curved in a similar way within the albumen. In Grasses it is situated at the base of the seed, and outof the seed, and outside the albumen (Fig. Fig. 386. Seed of the Red Campion (Lychnis), out 321). In the Poppy the embryo is in the axis, but is curved or arcuate, in Geranium the cotyledons are twisted and doubled, in Convolvulus they are corrugated, and in the Potato and in Bunias they are spiral. In some Cruciferous plants the cotyledons plants the cotyledons

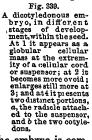

are bent like a leaf folded laterally on its midrib, and they are then called conduplicate, and marked o>; in other Cruciferous plants, they are flat, and the radicle is either bent along their edges, as in Wallflower (Fig. 337, r), and marked o =; or lies on the back of one of them, as in Rocket (Fig. 338, r), and marked o ||. In the former case, the cotyledons c are accumbent, in the latter incumbent. Some authors speak of the position of the embryo not merely in reference to the seed, but also in reference to the fruit. This is apt to lead to confusion. A superior or ascending radicle is the name given by them when it points to the apex of the fruit, while an inferior or descending radicle points to the base of the fruit; a centripetal radicle points to the centre or axis of the fruit, while a centrifugal one points in the opposite way.

In some plants, the embryo is entirely cellular and has no cotyledons. They are denominated Acotyledonous. They correspond to Cryptogamic or flowerless plants. The embryo, in such cases, is called a Spore (Fig. 8). It gives off roots and stems from different parts of its surface, and not

from any fixed points. It may either be regarded as an Botany. ovule remaining in a cellular state, or as a simple cellular embryo. It will be noticed when treating of the organs of Cryptogamic plants.

Plants which possess cotyledons in their embryo (Figs. 57 and 61) are called Cotyledonous, and they are divided into those having two cotyledons (Fig. 59), and which are called Dicotyledonous, and those having one (Figs. 60 and 63), called Monocotyledonous. The former correspond with the Exogenous division of Phanerogamous or flowering plants, the latter with the Endogenous. A dicotyledon ous embryo at first appears in the form of a cell (Fig. 333, e), the production of which in the embryo-sac depends on

the application of the pollen to the stigma. This cell is nucleated, and develops others in succession, until the embryo assumes the appearance of a congeries of cells suspended by a cellular filament (suspensor) as shown in Figure 339, 1. The globular cellular mass becomes afterwards more elongated, and passes through the stages 2 and 3 of Figure 339 until it assumes the appearance seen at 4, having an oblong or cylindrical form, with one extremity, a, undivided, and the other, b, lobed or notched. The undivided portion is the radicle (young root), and it may be considered as part of the rudimentary axis, from one end of which the roots are given off, and from the other the primary

bud or plumule. The split portion of the embryo is composed of two lobes or cotyledons, formed at one node, and

placed opposite to each other.

The cotyledons vary in their consistence, being sometimes leafy, at other times fleshy. They are sometimes so large as to form the great bulk of the seed, as in the Bean, Pea, and Almond. They form the first bud of the axis, which may thus be said to consist of a radicular and cotyledonary portion—their point of union being the Collum, neck, or crown. The part interposed between the neck and the cotyledons, which is often very short, is sometimes called the *Cauliculus* or *Tigellus*. The dicotyledonous embryo then is composed of two leaves or two unifoliar phytons, as they are called, united together so as to form one axis. The sheathing lower part of the cotyledons helps to form the caulicule; and from the axil of the cotyledons, or from the axis between them, is produced the plumular or gemmular bud (Fig. 59, gg), which forms the stem and leaves. This embryo may be represented by the ideal Figure 340, in which b is the axis or tigellus, a the radicular portion, connected with the soil and darkness, d the two cotyledons, united at their lower part so as to form the tigellus, and e the primary bud or plumule, connected with air and light. The embryo may be called a bifoliar phyton.

Although this is the usual state of the embryo in Exogens, nevertheless there are a few exceptions. In some Exogens without leaves, as the Dodder* and Rafflesia, the cotyledons are also suppressed. The embryo of these plants has a resemblance to the spore of Acrogens. In Cone-bearing plants, as the Pine, Spruce, Fir, and Cedar, the cotyledons are split by collateral chorisis, so as to be divided into several (Fig. 341), and this has given rise to the term polycotyledonous applied to them. The cotyledons of the Geranium and Lime-tree are divided into lobes. Accidental divisions are also seen in the cotyledons of the Sycamore and Rue. In Schizopetalon and some other Cruciferæ, the cotyledons are usually bipartite, so as to appear to be four.

A monocotyledonous differs from a dicotyledonous embryo in having only one cotyledon or seed-leaf (Fig. 63, c). It is composed of an axis having a radicular portion, r, and a cotyledonary portion, c, and it may be represented by a fig. 8.

Botany. single leaf or a unifoliar phyton. In Figure 342 is given an ideal representation of a monocotyledonous embryo, with its tigellus or axis, b, having a radicular portion, a, one coty-

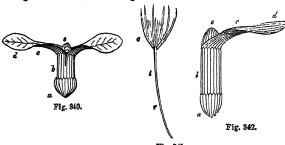

Fig. 341.

Fig. 341.

Fig. 340. Ideal representation of a dicotyledonous embryo or bifoliar phyton, with its radicular extremity, a, its two cotyledons, de, with their sheathing bases embracing the axis, b, and the primary bud, c. A dicotyledonous plant may be considered as composed of a series of such bifoliar phytons.

341. Polyocotyledonous embryo of the Pine (Pinus) beginning to sprout. The axis, t, shows its radicular portion, r, and cotyledonary portion, c. The cotyledons, c, appear to be numerous, but this is considered as being produced by chorisis or the division of two. Within the cotyledons the primordial leaves are seen, constituting the plumule or first bud of the plant.

342. Ideal representation of a Monocotyledonous or unifoliar phyton. The axis, b, has a radicular extremity, a, and a plumular bud, c. The cotyledon, d. c, has a sheathing base embracing the axis, and giving off the plumular bud, c, from its axil. A monocotyledonous plant may be considered as composed of a series of such phytons.

ledon. d.c. with a sheathing base, and a bud in its axil. c.

ledon, dc, with a sheathing base, and a bud in its axil, e, which rises as the stem. When this embryo is examined in the seed, it frequently exhibits no marked divisions—the cotyledon being coiled round the axis like a sheath, and embracing the plumule so as to conceal it. This is the case with the embryo of the Coco-nut. Sometimes a monocotyledonous embryo has more than one cotyledon. In that case, the second cotyledon alternates with the first, being produced at a second node, which is separated from the first

Transformations in Seeds.—Changes take place in seeds by abortion, degeneration, and union. There are few plants in which all the ovules become perfect seeds. Many are suppressed during the progress of growth, so that frequently one seed is developed at the expense of several ovules. Sometimes the seeds are converted into leaves. There is usually a single embryo in each seed, but cases occur in which a plurality of embryos is produced. This is a very common occurrence in the Orange, Cycas, and Cone-bearing orders. In the case of the two latter orders, the suspensor often ramifies so as to produce numerous separate embryos on its branches. These embryos are frequently abortive. In the seed of the Fir there are certain cellular bodies, called corpuscles by Brown, which give origin to filaments by which the embryos are suspended. Accidental union of embryos also take place.

II.—REPRODUCTIVE ORGANS OF FLOWERLESS PLANTS.

It has already been stated that Flowerless or Cryptogamic plants are composed either entirely of cells, as occurs in Seaweeds and Mushrooms; or of cells and vessels united, as seen in Ferns, Mosses, and their allies. The vascular tissue consists chiefly of pleurenchyma (Fig. 24) with closed spirals, annular (Fig. 32), and scalariform vessels (Fig. 34). In the simplest plants, as Protococcus (Fig. 343), the cell performs all the functions necessary for the nourishment and reproduction of the plant. In the more complicated Flowerless plants, there are some organs specially adapted for nutrition or vegetation, and others for reproduction. In the higher Cryptogams, there are roots, conspicuous stems, and leaves, for the purposes of nutrition, and certain special organs destined for reproduction. As these tribes produce a foliaceous axis or corm, they are denominated Cormogens or Cormophytes, and when their stems are woody, they present the acrogenous structure already described. In the lower Cryptogamics there are no true roots, nor stems,

nor leaves, and their nutritive and reproductive organs are Botany. frequently assimilated. These tribes, from having no foliaceous axis, but simply a cellular expansion, have been called Thallogens or Thallophytes.

While the nutritive organs of Cryptogamic plants bear

a greater or less resemblance to those of Phanerogams, the case is very different with the reproductive organs. Cryptogams have no flowers and no true seeds; they are propagated by cellular bodies denominated Spores (Fig. 344), which are cells capable of sprouting and forming new plants, (Fig. 348), and which some have called cellular embryos without cotyledons, or leafless phytons. The plants are consequently A cotyledons. gans. Cryptogams donous.

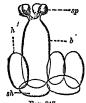

The term spore $(\sigma\pi\rho\rho)$, seed) should be confined to the ultimate germinating cell of Cryptogamics. It is frequently, however, applied to the cell in which the true spores are formed. Hence spores have been called simple or compound, according as they are formed by one or by several cells. The term Sporidium is applied to the compound spore of Lichens

Spores are developed either in the interior of the cell which gives origin to them, or on the outside of it. In the former case, they are called Endospores, in the latter, Exospores or Gymnospores. In Protococcus (Fig. 343), the fructification consists of numerous spores in the interior of a mother-sac, more or less spherical; in Palmella (Fig. 11), the mother-cell contains two or four spores; while in Vaucheria, only one spore is produced. A cell containing one, four, six, eight, or numerous spores or sporidia, receives the name of Theca (Fig. 346, t).

The exospores or naked spores in certain Moulds consist of elongated filaments which are formed by a series of cells placed end to end (Fig. 18, c). When ripe, the cellules separate. In Botrytis a single spore only constitutes the exospore, while

in Cantharellus there are two, and in Agarics four (Fig. 347, sp). Leveille called the mother-cell, on the exterior of which one, two, four, or many spores are formed, a Basidium (Fig. 347, b). In Agarics, the basidia bearing four spores at their extremity are in general united together so as to form a tissue called Hymenium (Fig. 347, h). In Lichens, Sphærias, and Pezizas, the thece containing four, six, or eight spores or sporidia placed one above the other are often separated by filaments or Paraphyses (Fig 346, p); and the united thece and paraphyses constitute the hymenium, which is placed so as to form a tissue called Hyme-

on the tissue forming the cortical or medullary layers called the subhymenium (Fig. 347, sh). The spore-bearing tissue is sometimes called generically the Excipulum; it may be flat, as in Usnea, and is then called Apothecium, or hollow, as in Peziza, and then called Receptacle; or it may form a closed cavity with an opening (ostiolum) only at one part, and then it is called a Conceptacle. In Ferns and Mosses,

Botany. the hollow cavities containing the spores receive the name of Sporangia (σπορά, seed, ἄγγος, a vessel) or spore-cases.

Spores are generally regarded as being produced by the agency of certain organs equivalent to the stamens and pistils of Phanerogams. These organs have been demonstrated more or less completely in all the orders of Cryptogamic plants, and they have received the names of Antheridia (Fig. 348, a), and Pistillidia or Archegonia (Fig.

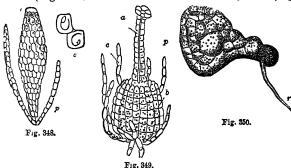

Fig. 348. Antheridium, a, of the Hair-moss (Polytrichum), consisting of cellules, c, containing phytozoa couled up in their interior. The phytozoa have a thickened extremity, whence proceeds a tapering tail-like process. Along with the antheridium are two separate filaments or paraphyses, p, which are probably abortive antheridia.

349. Pistillidium of Liverwort (Machanta), surrounded by its cellular covering, b, and by septate filaments called paraphyses, c; and surmounted by a style-like calyptra, a.

350. Spore, s, of a Forn (Peteri tongifotia) sprouting, giving off a root-like process, r, and a flat cellular expansion, p, called the pro-thallus or pro-embryo. On this expansion antheridia and pistillidia are said to occur.

349—ἀρχὴ, beginning, and γονὴ, offspring), the former representing the stamens or the male, the latter the pistil or the female. The antheridia were early noticed by Hedwig in the case of Mosses, and their presence has of late years been detected in nearly all the Cryptogamic tribes. In Mosses and in Liverworts antheridia and archegonia occur on the fully-developed plants. In Ferns and Horse-tails, they are seen on a cellular structure of a leafy character, called the Proembryo or Pro-thallus (Fig. 350), developed from the spores.

In antheridia there have been detected cells containing moving filaments, Phytozoa, or Spermatozoids, or Antherozoids (ζωον, an animal—Fig. 348, c). Each phytozoon (φυτον, a plant, and ζωον, an animal) is formed in a special

cell, is rolled upon itself in a spiral manner, and escapes either by a pore or by a dissolution of the wall of the cell. It is often furnished with slender threads at one extremity (Fig. 351). In the thecæ and sporangia, also, of many Cryptogamics, certain moving spores have been observed, furnished with vibratile threads or cilia (Fig. 8). These spores have been denominated Zoospores or Sporozoids (σπορά, a seed, ζῶον, an animal, ecos, resemblance). Their motions seem to be connected with vibratile processes which vary in number, and which proceed from different parts of the spore.

Fig. 351. Fig. 351.
Phytozoon or spermatozoid, from the antheridum of Chara.
It has two long vibratile processes at one extremity, and to these its movements

Filices or Ferns.—These Cryptogamic plants are composed cellular and vascular tissue. They have roots, leaves, an of cellular and vascular tissue. acrogenous stem, containing scalariform vessels, and an acotyledonous embryo. The stem or Caudex either rises conspicuously into the air, as in the case of Tree-ferns with their elegant foliage, or it appears as a rhizome running along the surface of the earth or under ground, as seen in the native Ferns of Britain. The trunk of Tree-ferns is hollow when fully formed, generally simple, sometimes dichotomous, having on the outside leaf-scars which display the markings of the vascular bundles (Fig. 88). The leaves. which are called *Fronds*, are produced at the summit of the stem, and they form a very graceful crown or coma. In the

young state, they are rolled up in a circinate manner, so as to resemble a crosier (Fig. 100). They consist of veins and parenchyma, the former being usually of equal thickness throughout, and divided in a forked (furcate) or reticulated manner. The epidermis has stomata, but they are not very numerous. The fronds bear the fructification. In some instances they produce bulbils or gemmæ, which, when separated from the plant, take root and give rise to new individuals; such Ferns are called Bulbiferous or Gemmiparous.

The fructification in its fully developed state appears as Sporangia, or Spore-cases, situated on the veins on the back, or on the margins of the leaves, containing spores. These spore-cases are arranged in clusters (sori) of a round (Fig. 352, s) or elongated form, and they are either naked

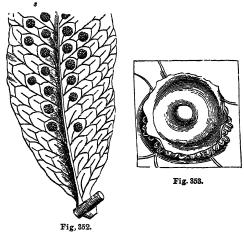

Fig. 352. Frond (fructiferous leaf) of a Fern (Niphobolus), showing sori, or round clusters of sporangia at the ends of vens. As these sori are on the back of the frond, the Fern is called dorsiferous.

353. Sorus or cluster of Sporangia of a Fern (Aspidium trifoliatum). The Sporangia are coveged by an industum or involuce, derived from the epidermis of the frond. The involuce is round (orbicular), and attached by its centre in an umbilical manner. The annulate sporangia are seen at the lower edge of the involucre.

or covered by a layer of the epidermis, which forms an Involucre or Indusium (Fig. 353). This indusium presents various forms, and is pushed off during growth in different ways, according to its mode of attachment to the leaf. It sometimes happens that the sporangia, in place of being in clusters on the back of the frond, as in the dorsiferous fructification, appear in the form of a simple or branched spike, as in Osmunda.

The sporangia commence as cellular buds from the parenchyma. Some of the cells constitute the stalk when present (Fig. 354, p), others form the sporangium, s, in the interior of which spores are formed. It frequently happens that the cells outside the sporangium form an Annulus or ring (Fig. 354, a), which is either vertical, and attached by its base, as in Polypody, or horizontal and free, as in Hymenophyllum. The cells composing the ring have walls which vary in thickness on the inner and outer side, and by their unequal contraction finally rupture the delicate sporangium, so as to allow the spores to escape. The ring is very obscure and imperfect in some Ferns, as Osmunda, and it is wanting in Moonwort and Adder's-tongue, and in many other Ferns. Hence, some Ferns are called annulate (having a ring), others exannulate (not having a ring). The spores are covered by a double membrane, and the outer layer is marked with points (Fig. 344). These spores, during germination, give rise to the pro-thallus or proembryo (Fig. 350), bearing the antheridia and archegonia.

Equisetaceæ, or Horse-tails.—The plants of this Cryptogamic order exhibit cells, vessels, a siliceous, striated epidermis, and stomata. They have roots, rhizomes, or underground stems, and aerial branches, but no true leaves. The rhizomes sometimes extend to the depth of many feet.

The stalks sent up from the rhizomes are hollow and jointed, the articulations being separable, and surrounded by toothed sheaths (Fig. 355, s).

The fructification in its advanced state consists of sporecases inclosing spores, attached to the under surface of shield-like hexagonal scales (Fig. 356), and collected into a

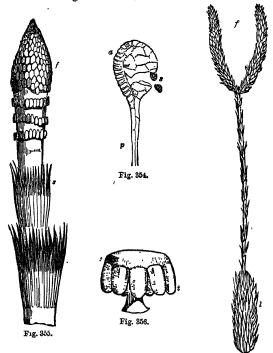

Fig. 357

Fig. 354. Mature sporangium of the Male Fern (Lastrea Filiz-mas). It is supported on a stalk, p, some of the cells of which form an elastic ring or annulus, a, round the spore-case. The spore-case, s, opens at the side to discharge the spores.

355. Fructification of a species of Horse-tail (Equisetum Telmateia). The stalk is surrounded by a series of membranous sheaths, s s, which are fringed by numerous sharp processes or teeth. The fructification, f, is at the extremity of the frond, in the form of a pyramidal mass of polygonal scales, bearing spores on their under surface.

356. Polygonal scale, s, of a species of Horse-tail (Equisetum), bearing membranous sacs, t, which open on their inner surface to discharge spores.

memoranous sacs, t, which open on their inner surface to discharge spores.

357. Fructification of a Club-moss (Lycopodium clavatum). The branch is covered with minute pointed leaves, t; from it proceeds a stalk bearing at its extremity two spikes, f, consisting of modified leaves, with fructification.

common pyramidal head (Fig. 355, f). The scales (Fig. 356, s) bear on their under surface a circular row of membranous sacs elongated like teeth, t. The sacs open towards the centre of the scale, or that part to which the stalk is attached. Within these sacs there are mother-cells which produce each a single spore. This spore is provided with two elastic spiral appendages, which at first completely cover the wall of the mother-cell and inclose the spore, but finally spread out so as to burst the walls of the sac (Fig. 9, a, b). The spore, when sprouting, produces a proembryo or pro-thallus, which at first appears as a green-lobed leaf supported on a stalk. The lobes of the proembryo extend and subdivide until a number of cellular septate tubes are produced, containing green matter. It is in this state that bodies resembling the antheridia of Ferns have been detected, as well as peculiar cells, which have been regarded as equivalent to archegonia.

Lycopodiacea, or Club-mosses. These plants have creeping stems or corms, which produce leafy branches, having some resemblance in general appearance to Mosses. Structurally they consist of cells and vessels, the latter occurring in the form of woody and annular vessels, which occupy the axis or central part of the stems. Roots are given off from the primary stem, as well as from different parts of the branches. The leaves are small and sessile,

imbricated (Fig. 357, 1), or verticillate, and on their epi- Botany. dermis stomata exist in small quantity. The fully-developed fructification occurs in the axil of leaves, which are often collected together in the form of a spike f. The fructifi-

cation is of two kinds, one being kidney-shaped, two valved cases (Fig. 358), containing minute cells, which are discharged in the form of yellow dust, known as Lycopode powder, and used, from its inflammable nature, in place of sulphur. The other kind of fructification consists of a roundish and somewhat four-sided body, called by Müller Oophoridium (ŵòv, an egg, and \$\phi\phi\phi\epsilon\text{to}\text{ known as Lycopode pow-

Fig. 359. Fig. 358.

taining four large spores in its interior, and opening by two valves (Fig. 359). These large spores, called *ovules* by some, germinate and reproduce the plant. While the first mentioned organ is considered by some as an antheridium containing grains like those of pollen, the latter is looked upon

as the pistillidium with ovules.

Marsileaceæ, Rhizocarpeæ, or Pepperworts. — These plants have creeping stems with leaves, which are divided into three or more cuneate portions, and have a circinate vernation. The leaves have stomata and veins. The stem increases by its extremity. It contains a central vascular bundle consisting of woody and scalariform vessels surrounded by parenchyma. The fructification is produced at the base of the leaf-stalks. It consists of Sporocarps (σπορά, a seed, and καρπὸs, fruit), or ovoid sacs inclosing organs of re-

production. In Figure 360 is represented the two-valved sporocarp or involucre, s, of Marsilea open, and giving out a cellular cord (called by some the midrib of the modified leaf forming the involucre), which at first was curved in a ring-like manner so as to unite the valves, and which finally is detached at one end, p, bearing the reproductive spike-like masses, f, on its surface. These masses consist of antheridia and pistillidia inclosed at first in sacs, and attached to mucilaginous placentas. The pistillidia give origin to the sporangia or ovules, each containing a single germinat-

Musci or Mosses.—These plants have stems bearing minute cellular leaves. The stems consist of cells which in the periphery are polyhedral, while in the centre they are elongated. There is no pleurenchyma nor true vascular system. In many Mosses the stem terminates at a certain epoch, by bearing the organs of reproduction. Such stems are determinate, and the Mosses are called Acrocarpous (ἄκρος, top, and καρπὸς, fruit). In other cases the principal stem ends in a leafbud, and continues to elongate, the organs of reproduction appearing on lateral branches. Such stems are indeterminate,

and the Mosses are called Pleurocarpous (πλευρά, side, and καρπός, fruit).

Fig. 860.

Fructification of a species of Pepperwort (Marsilea Fabri). The sporocarp, so pens to give out a peculiar cord or peduficle, p, which at first was curved in a ring-like manner. This cord bearsspike-like fructification, f, consisting of artheridia and pistillidia inclosed in saos, and attached to a common axis or placents. The leaves, when produced on the stem, are called caulinary; when they surround the reproductive organs they are called perichætial (περί, around, and χαίτη, stalk). The latter are usually more approximated than the others, and

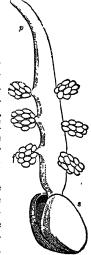

Fig. 360.

Botany. form a sort of rosette, in the centre of which the reproductive organs are situated. The leaves are very thin in their texture, and are frequently composed of a single cellular layer. The cells usually contain chlorophyll, but sometimes, as in Sphagnum, they are colourless. The cells are either uniform in their size and appearance, or a certain number towards the centre are elongated, so as to form veins or ribs. The phyllotaxis of Mosses is usually 1, 2, or 3. Buds, or what are called Innovations, are often produced in the axil of the leaves. These buds, when detached, become new plants.

Occasionally the reproductive organs of Mosses have a peculiar leafy covering or Perigone, formed by the adhesion of three or six small leaflets, which are quite distinct from the perichætial leaves. The organs of reproduction are of two kinds: one, consisting of cylindrical, pear-shaped, or ellipsoidal stalked sacs, containing minute cells, with phytozoa or spermatozoids in their interior (Fig. 348); the other being also stalked sacs, of a more or less spherical form, containing germinating spores. The former constitute the antheridia, the latter the pistillidia or archegonia. These organs sometimes exist together on the same plant; at other times they are on separate plants. In the former case the Mosses are monœcious, in the latter diœcious. When both these organs are not only on the same plant, but also surrounded by the same perigone, the term hermaphrodite has been applied by some.

The antheridia of Mosses are produced from little clusters of leaves, which differ from those of the stem. They appear in the form of cellular, cylindrical, clavate bodies (Fig. 348, a), containing at first a mucilaginous fluid, and finally very minute, quadrilateral cellules, c, (sometimes called Zootheceζωον, animal, θήκη, a sac), in each of which a spiral phytozoon is seen. The antheridia dehisce by irregular openings at their apex, so as to discharge their contents. Along with the antheridia there are cellular jointed filaments (Fig. 348, p), called Paraphyses, which are considered to be an abortive state of these organs. The archegonia, often mixed with paraphyses or abortive filaments, arise also from small clusters

or rosettes of leaves (Fig. 361, f), and appear in the form of spherical or obovate bodies having an outer envelope (epigone) and a central cellular nucleus. In the progress of growth, the central portion increases and rises upwards, and, at the same time, the epigone is ruptured near the base one portion of it remaining below in the form of a small sheath (vaginula), the other being carried up on the fruit-bearing stalk in the form of a Calyptra (Fig. 361, c). This calyptra is sometimes split at one side (Fig. 361), so as to become dimidiate (halved), and at other times it is either entire or split equally all round the base, and it is then called mitriform. The nucleus or central mitriform. The nucleus or central portion, when fully developed, constitutes the Sporangium. The sporangium is usually supported on a stalk or seta (Fig. 361, p), formed by the lower cells of the nucleus. The seta is often twisted, and, from its hygrometric property, it produces changes in the position of the sporangia for michithe callyptra has fallen. The seta is twisted, and displays hygrometric properties.

Fig. 361.

dryness or moisture of the atmosphere. A species of Funaria or Cord-moss, receives the name of hygrometrica, on this account.

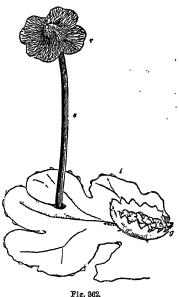

The sporangium in its young state is a mass of cellular VOL. V.

tissue, the cells of which are homogeneous, and contain Botany. green matter. When mature, it is an urn-like body (Fig. 20), with a cellular central axis called columella, and a cavity containing spores. In some instances the sporangium is indehiscent; in other cases it opens either by four lateral valves, as in the Split-moss (Andræa), or by means of a lid called an Operculum (Fig. 20). Sometimes there is a thickening or swelling called apophysis, at the union of the seta and urn.

When the operculum is removed, the opening (stoma or mouth) of the sporangium is seen. This is sometimes entire, as in Mosses called naked-mouthed (qymnostomi, yuuvos, naked, and στόμα, month); at other times it is surrounded by a Peristome (περὶ around, and στόμα, mouth), formed by prolongations and divisions of the two inner parietal layers of the sporangium (Fig. 20, p). The peristome consists of one or more rows of hygrometric cellular teeth, which are either four, or some multiple of that number. When there is one row of teeth, the Mosses are called

Aploperistomi ($\delta\pi\lambda\delta$) single); when there are two rows, the Mosses are called Diploperistomi (διπλόος, double). The peristomatic processes (teeth) are sometimes twisted as in Tortula. In some Mosses the inner parietal layer appears as a membrane called Epiphragm or Tympanum, stretched across the mouth, from the walls of the sporangium to the columella.

Hepaticæ or Liverworts .- In these plants the vegetative system. (organs of nutrition) consists either of a simple cellular expansion or thallus, or of an axis bearing cellular leaves. A In Marchantia this thallus (Fig. 362) bears the organs of reproduction, as well as cup-

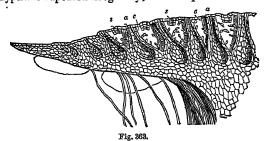

species of Liverwort (Marchantia polymorpha), with its green thallus, t, bearing a cup-like body, g, in which minute cells or free buds are seen, and a stalked receptacle, s r. In the substance of the disk-like receptacle, r, cells are produced containing phytozoa. These are considered antheridia.

like bodies with toothed edges, containing little germs or bulbils, g, which are not traced to a reproductive process, and differ from buds, in being contained in peculiar organisms.

In Hepaticæ, the reproductive organs consist of zoothecæ or antheridia, and archegonia or pistillidia, either on the same or on different plants. The antheridia are small cellular sacs of a globular, ovoid, or flask-like form, (Fig. 363). They have a single or double cellular covering, inclosing viscid matter, in which are developed four-sided cells, in each of which is a small filiform body, rolled up in a circular manner, and displaying rapid movements. These bodies, called phytozoa, are finally liberated, and unrol themselves, appearing as filaments swollen at one extremity, and gradually tapering to the other.

The archegonia or pistillidia of Hepaticæ are either situated in the substance of the thallus, as in Riccia, or they are raised upon stalks, as in Marchantia and Jungermanniæ. In Marchantia these stalks bear radiated receptacles on the under surface of which the sporangia are placed. These sporangia have a membranous covering called epigone or calyptra, the upper end of which elongates like the neck of a bottle (Fig. 349 a), so that the

pistillidium resembles a pistil, with its ovary, style, and stigma. When the sporangium is raised on its stalk, the calyptra is ruptured irregularly; its lower portion remaining

Vertical section of the disk-like receptacle of Liverwort (Marchantia), showing the antheridia, a a, in its substance. These antheridia are flask-shaped sacs containing phytocary cells. They communicate with the upper surface, and their contents are discharged through it. Between the antheridia there are air cavities, cc, connected with stomata, ss.

in the form of a sheath round the base of the stalk. The pistillidium, thus formed by the central cellular sporebearing sac and the epigone, is surrounded also by a cellular sac called the perigone (Fig. 349, b), which begins in the form of a ring at the base, and ultimately forms a cup-like covering. Occasionally there are certain cellular filaments, or perichætial leaves, surrounding the perigone (Fig. 349, e). In Marchantia the perigone incloses a single pistillidium; in Jungermannia it incloses several, but only one is developed. Along with the spores in Hepaticæ there are elastic spiral fibres called elaters.

Lichenes or Lichens—are cellular plants growing on stones, on the surface of the earth, and on trees, and taking up nourishment by all points of their surface. They belong to the Thallogenous division of Cryptogamics, in which no vascular tissue is seen. Their vegetative system varies much in its form and appearance. Sometimes it appears as fine pulverulent matter in the form of a leprous or mealy crust; sometimes it is a foliaceous expansion, as in Parmelia (Fig. 364), and in Iceland Moss; sometimes it is in the form of filaments, as in Archil, of horn-like processes, or of branching stalks, as in the Rein-deer Moss; and sometimes it is a gelatinous mass.

The vegetative system is sometimes called the thallus. It consists of two layers of tissue, one called cortical, in which the cells are more or less rounded, the other medullary, in which there are both round and filiform cells. The spherical cells of the medullary layer (Fig. 365, g), are generally filled with green matter, and, in certain circumstances,

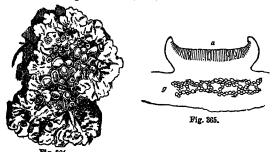

Fig. 364. A Lichen (Parmelia), with its cellular expansion (thallus), and its rounded apothecia, or spots of fructification.

365. Vertical section of an apothecium and thallus of a Lichen. Rounded free cells, g, of a green colour, and called gonidia, are seen in the centre of the thallus. These gonidia, which are called free buds by some, are capable of germinating and reproducing the plant. They constitute the active part of the Lichen, and are surrounded on each side by integumentary layers. Sometimes they burst through the surface of the thallus. The apothecium, a, consists of thece and paraphyses. Its upper surface is often coloured and covered by a perithecium.

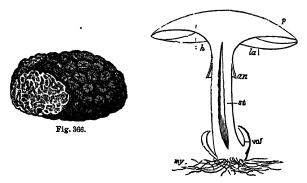

they become detached and form separate individuals. These green cells have received the name of Gonidia.

The reproductive organs of Lichens consist of thecæ

(sporangia of some), often accompanied with paraphyses. Botany. While these represent the archegonia or pistillidia, there is no good evidence of the existence of true antheridia. Itzigsohn has recently indicated the presence of antheridia containing spermatozoids, but his observations have not been confirmed by Tulasne and others. The thecæ contain four, eight, twelve, or sixteen sporidia (Fig. 346), which are cells with spores in their interior. The sporidium in its early state consists of two nucleated cells (Fig. 345), which in the progress of growth become changed, so that ultimately the mature sporidium contains numerous minute spores. The thecæ and paraphyses are usually united together, so as to form a mass of fructification of a circular, cup-like, globular, or linear form. The fructification, when circular, is called Apothecium and Patella (Fig. 364), when linear, Lirella. Sometimes the fructification is covered by a cortical layer of cells (perithecium) varying in colour, black, red, or pale, which ultimately gives way, either by a pore or by irregular dehiscence. This is seen in what are called Angiocarpous Lichens.

Fungi.—These are cellular plants having neither leaves. nor stems, nor roots. The organs of nutrition or vegetation consist of whitish anastomosing filaments called Mycelium (μύκηs, a fungus) or spawn (Fig. 18, m), which spread like a network through the substances on which the Fungi grow. From this network proceed bodies resembling globes, circular disks, mitres, cups, and coralline branches, which bear the organs of reproduction. The mycelium is developed either under ground, or in the interior of the substance on which the plant grows. The filaments of the mycelium are composed of elongated colourless cells.

The organs of reproduction are produced at different points of the mycelium, sometimes solitary, sometimes several together. They at first appear as small tubercles composed of very minute hexagonal cells. These tubercles increase and present different phenomena according to the nature of the plant to which they belong. Thus in Ægerita, the tubercle, after attaining its full development, is covered with filaments, each bearing a spore at its extremity; in Peziza, it is hollowed out into the form of a cup more or less deep, the interior of which is lined with thecæ or asci; in Agaricus,* it produces a pileus or cap-like body borne on *Plate a long stalk which comes from the interior of the tubercle, CXXXVI. and bears the fructification externally; in Lycoperdon it figs. 5 & 6. forms in its tissue numerous lacunæ, from the circumference of each of which are produced elongated cells bearing four spores on their surface. Some Fungi vegetate under the surface of the ground, and either produce their fructification

there, as the Truffle (Fig. 366), or above ground, as the

Fig. 366. The Truffle (Tuber cibarium), a subterranean Fungus, with a black tuberculated or warty external covering, and a white cellular interior containing sportferous cells.
 367. Vertical section of a Mushroom (Agaricus campestris); my, mycellum or spawn; vol. remains of volva or wrapper; st, stipe or stalk; an, annulus orring, being the remains of the velum, veil, or cortina; la, lamells or gills of the hymenium, λ; p, the pileus.

Mushroom (Fig. 367). A very large number, however, are

developed as parasites in the interior of living or dead organized bodies.

* Plate

The organs of reproduction of Fungi* are spores, CXXXVI. either naked or contained in thecæ or asci, which are mixed with certain filaments called antheridia. Little is known in regard to the latter. When spores are produced in the interior of distinct sacs, called *Thecæ* or *Cys*tidia (Fig. 368, cys-κύστις, a bladder), they are denomi-

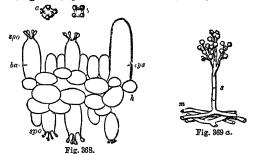

Fig. 368. Portion of a lamella or gill of the Mushroom (Agaricus campestris), out transversely, showing the two lateral surfaces bearing basidia, bas, with four spores, spo, at their apices, and cystidia, cys, or sacs containing minute cells. The hymenium is marked λ. At α and b are represented the four spores.
... 369 α. A species of Mould-fungus (Botrytis), consisting of a mycelium, m, bearing a septate cellular stalk, s, which branches at the apex, each division bearing a rounded spore.

nated *Endospores*, and the plants are said to be thecasporous; when they are developed on the exterior of sacs called Basidia (Fig. 368, bas—βάσις, foot), they are denominated Exospores, and the plants are basidiosporous; when produced in the midst of a gelatinous mass, without any evident organization, they are called Myxospores (μύξα, mu-

cus), the plants being myxosporous.

The fructification is composed either of a single transparent colourless cell, of a rounded or spindle-like form, at the end of each filament (Fig. 369 a); or it is composed of several cells united in a linear series (Fig. 18) or irregularly. The cystidia and basidia are either monosporous or tetrasporous (Fig. 368, spo). When either of these kinds of fructification are united into a mass along with paraphyses, they form what is called the Hymenium (Fig. 368, hύμην, a membrane). The hymenium is either naked, as in the Hymenomycetous Fungi, or it is inclosed in a membrane called *Peridium*, as in Gasteromycetous Fungi. This membranous covering may be either single or double.

In the Mushroom (Fig. 367) and other species of Agaricus,* the following are the usual organs observed:-A my-CXXXVI. celium or spawn, my, developed under ground, bearing tufigs. 5 & 6. bercles which consist of the reproductive organs inclosed in a volva or wrapper. This volva, vol, is ruptured in the progress of development. The Agaric is then seen to be composed of a pileus, p, supported on a stalk, st, called a stipe. On the lower side of the pileus is the lamellar hymenium or gills, la, bearing spores. The hymenium was first covered by the veil or indusium, which finally gives way, leaving only a ring, an, round the stalk.

Alga.—Under this name are included numerous plants which grow in the sea, in rivers, lakes, marshes, and hot springs. Their structure is such that they can only grow in water; when exposed to the air they wither and cease to grow. They have no true leaves and no proper stem, but consist of a thallus or cellular expansion which varies in colour-being brown, red, green, or yellow. In some of the larger Seaweeds, as D'Urvillæa utilis and Lessonia fuscescens, the thallus is supported on a thick stalk, which exhibits in its structure the appearance of concentric circles. These stalks, however, are composed entirely of cellular tissue arranged in a peculiar manner. There is no vascular system and no woody fibre in their composition. Some species have root-like processes by which they are attached to rocks. These are only intended for fixing them to a spot

so as to allow the fronds to be properly exposed to the water, and they do not appear to act as special nutritive organs. The structure of Algæ is cellular, and the cells vary much in form. Some of the cells are round or elliptical, others square, others elongated. The absorption of nourishment takes place throughout the whole substance of the thallus. On the surface of some Algæ, as the Charas, carbonate of lime is deposited, and sometimes, as in Corallines, the whole texture is so permeated by this substance, as to become of a hard and stony consistence.

In Algæ the reproductive organs vary in their appearance. They consist of spore-cases, which are often aggregated together in Conceptacles (Fig. 369 b), along with Antheridia containing spermatozoids (Fig. 370, a). The spores are often united in fours in a mother-cell, forming a tetraspore (Fig. 371, t). There are also present in many

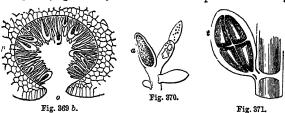

Fig. 369 b. Transverse section of a conceptacle of a Seaweed (Fucus vesiculosus), showing the spores in the coverings. p, and paraphyses liming the cavity. The spores escape by an ornice, o.

370. Antheridium, a, or Zootheca of a Seaweed (Fucus serratus), containing phytozoa.

371. Tetraspore, t, of one of the rose-coloured Seaweeds (Callithamnion oruciatum).

Algæ Zoospores or Sporozoids, which exhibit movements during a certain period of their existence, and are provided with filamentous vibratile processes.

In some of the lower plants of this order, such as Diatomaceæ (Fig. 13), an evident division of cells takes place; and in this way the plants are propagated. In Protococcus, the plant of Red and Green Snow (Figs. 56 and 343), and in Palmella, the plant of Gory Dew (Fig. 11), and their allies, the whole plant separates into cells, which may be considered either as buds or spores. In these plants no special reproductive organs have been detected. In some of the Confervæ, as well as in Diatomaceæ, the union of cells takes place in a singular manner, so as to give rise to the formation of germinating spores (Fig. 19).

Diatomaceæor Brittleworts—are among the simplest forms of Algæ. They are usually composed of united rectangular fragments of a brittle nature, which separate at certain periods of growth, and form new individuals (Fig. 13). The true Diatoms have a siliceous covering, so that they retain their form when dry, and are not destroyed by fire; while the division called Desmidieæ have no siliceous covering, and alter much on drying. In some of the plants of the order, the union of cells, called Conjugation, has been observed, similar to what takes place in Confervæ.

Confervas and their Allies.—These are plants usually of a green colour, consisting of round or cylindrical cells united (Fig. 17), so as to form a filamentous or a flattened thallus. In their simplest form they are seen in the Palmella (Fig. 11), consisting of a single globose cell, dividing first into two, and afterwards into four cells, which finally burst the mother-cell, and escape. Each of these divisions, like the parent cell, has the power of vegetating, and of dividing, by a merismatic process, into four, so as to multiply the plant. In Vaucheria, the terminal cell is concerned in the production of a germinating cell or spore, which has peculiar motions. In Achlya prolifera the terminal cell discharges numerous moving spores. In Zygnema and other Confervas (Fig. 19), the cells composing the filaments have the power of giving out lateral cellular processes, by means of which a union takes place, the result being the production of a spore, either in the tube between the filaments, or in one of the

*Plate

Botany. cells of the filaments. The cells in these plants appear to have different functions, and to correspond to the antheridia

and pistillidia of the higher Cryptogams.

Florideæ, or Rose-coloured Seaweeds.—These Algæ are usually of a rose or purplish colour, and consist of variouslyformed cells, arranged either in a single row, or in several rows, so as to form an articulated or an expanded flat and often divided thallus. The organs of reproduction are restricted to particular parts of the thallus, and consist of spore-cases, containing spores, frequently four in number, intermixed often with antheridia, or filaments containing spermatozoids, these organs being placed in the interior of conceptacles. The reproductive organs exist either in cavities of the thallus, or in distinct sacs produced on the surface of the thallus, or at the apex of some of its divisions. The occurrence of Tetraspores, (Fig. 371), or mother-cells containing four spores, is general in this division of the Algal alliance. The antheridia consist of septate filaments, the terminal cell of which assumes a clavate form, and contains phytozoa. The latter become free by the dissolution of the

walls of the cell. Besides the tetraspores, sacs (coccidia or ceramidia) of a rounded form exist, containing minute spore-like bodies (Fig. 372), which some call sporules. They appear to germinate, and differ from buds, in being contained in special sacs; some consider these cellular bodies as bulbils, which separate from the parent plant; others look upon them as another kind of spore.

Fucaceæ, or Brown Seaweeds.—I nese are usually brown or olive-coloured plants, growing chiefly in salt water. They consist of cells, which are united so as to form various kinds of thalli. Sometimes the thallus is supported on a distinct stalk, formed of elongated cells; and in the frond there occur also thickened cellular lines, having the appearance of veins. The cells of the thal-Fucaceæ, or Brown Seaweeds.—These cur also thickened cellular lines, having the appearance of veins. The cells of the thallus are often agglutinated together by a

of pear-shaped germinating cells or spores. gelatinous intercellular substance. The reproductive organs consist of spore-cases and antheridia, contained in conceptacles (Fig. 369 b), which are aggregated together in receptacles, or large club-shaped expansions, at the extremity or margin of the thallus and its divisions (Fig. 39, fr). The antheridia are sacs (Fig. 370, a) borne on jointed filaments, and containing moving phytozoa. Antheridia and sporecases are seen on the same or on different plants.

Characeæ or Charas.—These plants are considered as allied to Algæ, although they present many marked peculiarities. They consist of an axis formed by elongated tubular cells (Fig. 21), either transparent, or incrusted with carbonate of lime. From the axis arise branch-like processes, arranged in a verticillate manner. In the interior of the tubes of these plants, distinct circulating motions are seen under the microscope. The reproductive organs of Charas are of two kinds, one called the Globule (Fig. 373, g), a spherical body, containing filaments with phytozoa, the other denominated the Nucule (Fig. 373, n), an oval body containing a germinating cell or spore. The nucule is produced on the axil of a branch, and consists of a large central cell or spore, surrounded by

five cells, which are wound round it in a spiral manner, and ending in five tooth-like processes at the apex. The globule is usually placed immediately below the nucule, and consists of eight valves, inclosing a cavity in which the filamentous articulated phytozoary cells are contained. The cells in the interior of the valvular cavity are filled, like Botany. those on the flat portion of the valves, with red granules.

On the apex of cells projecting from the centre of each valve, there are numerous filaments (Fig. 374), composed of cellules containing minute escape from the cell,

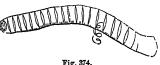

Fig. 374.

phytozoa, coiled up in a partitioned filament of Chara, consisting of a series of cellules containing pluy-tozoa, one of which is seen escaping in the form of a spiral thread.

and exhibit spontaneous movements (Fig. 351).

II.—PHYSIOLOGY OF THE REPRODUCTIVE ORGANS.

I.—PHYSIOLOGY OF THE FLORAL ENVELOPES.

The appendages of the flowers which assume a green colour perform the same functions as leaves, giving out oxygen under the influence of light. The cells of the floral leaves or bracts, and of the calycine leaves or sepals, commonly contain chlorophyll, which is produced under the agency of light by a process of deoxidation, carbon being fixed and oxygen separated. The bright-coloured parts of flowers do not appear to decompose carbonic acid; on the contrary, they exhale this gas. The corolla is associated with the thalamus or receptacle in producing abundance of starch, which is changed into sugar during flowering, so as to afford nutriment to the stamens and pistils. While the calyx and green parts of the flower are concerned in the elaboration of the juices under the influence of light, the corolla is more immediately concerned in the protection of the internal organs, in the formation of coloured juices, and in the production of amylaceous and saccharine matter. The quantity of starch accumulated in the receptacles of flowers is often large. This is well seen in Compositæ, such as the Artichoke and Thistle. The amylaceous matter during flowering in these plants becomes saccharine, and is absorbed by the flowers for their nourishment.

The flower, according to Saussure, in the exercise of its functions, absorbs oxygen gas, and gives out carbonic acid. The absorption of oxygen is carried on by the coloured corolla, along with the essential organs of reproduction. The organs of plants which consume most oxygen are those which wither most quickly, viz. the stamens, styles, and petals. The quantity of oxygen absorbed is much greater when the stamens and pistil are perfect than when they are abortive or wanting. A perfect flower, with the latter organs present took up more oxygen than one which had become double by the more or less complete conversion of

the stamens and pistil into petals. Thus

Common Stock, Single Red, consumed 11 times its vol. of oxygen. Double 7.7 ,,

,, Common Tuberose, Single g. " Double 7.4 " " Indian Cress, Single 8.5 Double 7.25

In proportion to their volume the essential reproductive organs absorb more oxygen than the entire flowers; and male flowers consume more oxygen than female ones.

At the same time that oxygen is absorbed there is a conversion of starch into grape sugar, an evolution of carbonic acid gas, and in many instances a very marked elevation of temperature, caused by the combination between the carbon of the flower and the oxygen of the air. The starch, which is stored up in the receptacle and at the base of the petals, by passing into the state of dextrin and grape sugar, becomes fitted for vegetable nutrition. At the same time important purposes are served in the economy of the plant. Thus the saccharine and honey-like matter which often collects in the cup of the flower, and sometimes in special pits or depressions, as in Crown Imperial (Fig. 55), attracts bees

*Plate

fig. 2.

Botany. and various insects, which are thus made instrumental in scattering the pollen. According to Vaucher, the saccharine matter is applied to the stigma and other parts of the pistil, so as to favour the application and bursting of the

grains of pollen.

An evolution of heat takes place during flowering; but from the large surface exposed, it seems to be in most instances carried off by the atmosphere as soon as it is developed. Cases occur, however, in which the temperature can be noted. Thus the flower of a Cistus showed a temperature of 79°, while that of the air was 76°, and those of a Geranium 87° when the air was 81°. Otto ascertained that the flowers of Victoria regia at Hamburg gave out heat when the anthers were mature. Mulder found the flower of Cereus grandiflorus 1° to 2° F. warmer than the atmosphere. M. Teysman at Burtenzorg, in Java, observed an elevated temperature in the male cone of Cycas circinalis.* By means of CXXXIV. an air thermometer Saussure found the flowers of Polyanthes tuberosa $\frac{1}{2}$ °, those of Bignonia radicans 1°, those of Cucurbita Pepo 1° to 3° F. above the temperature of the air.

The most marked instances of the evolution of heat, however, occur in the blossoms of plants belonging to the natural order Araceæ. In them the inflorescence consists of a thick fleshy spadix (Fig. 166) containing much starch, and bearing numerous male and female organs inclosed in a large sheathing bract or spathe. Senebier found that the temperature of Arum maculatum* rose to 15.5° F. above CXXXV. that of the air, and Dutrochet measured it from 25° to 27°. Goeppert states that the temperature of the spadix of Arum Dracunculus rose to 31.5° F. above that of the air surrounding it. Brongniart in 1834 found the temperature of Colocasia odora 19.8° F. above the air of the conservatory in which the specimen grew. From Dutrochet's examination of the spadix of Arum maculatum it appears that the maximum of temperature in the spadix occurred at 5.30 P.M., one hour and a half after the complete opening of the spathe, and that the heat was 18.7° above that of the surrounding air.

> The seat of the highest temperature changes during flowering. When the spathe opens, the staminal organs show the greatest heat; and after the pollen is discharged, their temperature falls, and the part of the spadix above them grows warm. Hubert states that the outer surface of the spadix is that in which the temperature is principally developed. The male organs of the Arum have a higher temperature than the female. There is also exhibited during flowering a daily maximum and minimum of temperature, which, however, do not appear to occur at regular periods. In the case of Arum maculatum, Dutrochet found the maximum temperature at 5.30 P.M., while Senebier noticed it after six in the evening. In Colocasia odora, Brongniart found the maximum at 5 P.M.; Vrolik and De Vriese, as well as Van Beek and Bergsma, at 3 P.M.; Hasskarl, in Java, at 6 A.M.; Hubert, in Madagascar, after sunrise. In the gardens of Paris, Amsterdam, and Leyden, Colocasia odora attains its maximum temperature at noon. The production of heat in Arum italicum, according to Saussure, attained its maximum from 4 to 7 P.M.

Brongniart gives the following results of his observations on Colocasia odora as regards the time and degree of maximum heat:-

DATE OF OBSERVATION.		Hour of Max. Tempera- ture.	Tempera- ture of Air.	Tempera- ture of Spadix.	Tempera- ture above Air.
Spathe opened March Pollen dis- charged,	$ \begin{cases} 14 \\ 15 \\ 16 \\ 17 \\ 18 \\ 19 \end{cases} $	3½ P.M. 4½ ,, 5 ,, 5 ,, 11 A.M.	76·1° F. 75·2 74·8 75·2 80·6 77·9	84·2° F. 93·2 93·2 95 95 95·3 82·4	8·1° F. 18 18·4 19·8 14·8 4·5

The rise of temperature bore an evident relation to the

development of the stamens and the emission of the pollen. Botany. and after the latter had taken place, the temperature felland the spadix withered.

Garreau made observations on the heat given out by the spadix of Arum italicum. In an experiment conducted on 8th June 1851, the atmospheric temperature being 66.2° F. he found that the mean heat per hour was 11.2° F., the mean of the oxygen consumed 76.6, and its mean volume, when compared with the organ as unity, was 169. The oxygen consumed during the 6 hours of the paroxysmal heat was 460 cubic centimetres, and that consumed during the 18 succeeding hours was 230, making in all, in 24 hours, 690 cubic centimetres. The quantity of oxygen consumed increased with the temperature. In three distinct experiments the results were-

No. 1. Mean heat, 9.9° F. Oxygen consumed, 16.1 cubic cent. - 11.2 16.9 No. 3. 13.1 17.3

Garreau says that the nature of the surface of the spadix of Arum seems to facilitate absorption. It consists of numerous projecting cells, giving a velvety appearance to the organ, with two or three open stomata. Saussure found that the blossom of Arum maculatum, when cold, consumed five times its volume of oxygen, but when warm, thirty times. In a flower during the paroxysm, he found that the spathe consumed five times its volume of oxygen, the bare portion of the spadix 30 times, and the part covered with flowers 132 times.

The relation which the evolution of carbonic acid bears to the heat produced is thus shown by Dutrochet:-

NAME OF ORGAN.	Mean Temp. above Air in 12 Hours.	CO2 evolved in 24 Hours.
Spathe of Arum maculatum Spadix of do. Male organs of do. Female organs of do. Female flower, Gourd	0·06° F. 18·00 12·00 2·7 0·16	Cubic centimetres. 4:0 38:0 135:0 10:0 7:6

The quantity of carbonic acid evolved is in direct proportion to the oxygen absorbed, and the degree of chemical action which takes place determines the amount of heat.

The presence and contact of oxygen gas is necessary for these phenomena. When the spadix of an Arum is put into oxygen gas, the heat is developed rapidly and powerfully, the maximum difference between the heat of the oxygenated spadix and another in the air varying from 5° to 12° F.; and when the spadix is placed in carbonic acid gas or nitrogen, the evolution of heat ceases. The production of heat is prevented by covering the spadix with olive oil, grease, tallow, honey, or starch.

Periods of Flowering.—The age at which different species of plants produce flowers varies. Some spring from seed and produce flowers in the course of a single year and die, others produce flowers the second year after germinating and then decay, while a third set continue to flower for many years in succession. Hence the division into annual (O), biennial (d), and perennial (4), plants. In some cases flowering is long delayed, and when it does occur the development of the flowering stalk takes place with great vigour and rapidity, and the plant dies after producing fruit and seed. Any cause, whether natural or artificial, which retards flowering, is attended with results of a similar kind more or less marked. When fruit trees have been in a non-flowering condition, they sometimes suddenly produce abundance of blossoms. A season in which blossoming has been scanty is often succeeded by one in which it is profuse. When the flower-buds are taken off early, it sometimes happens that an annual plant, such as Mignonette, is rendered biennial or perennial. The tree Mignonette is pro-

duced in this way. When plants grow in a rich soil it others a few hours later, others at mid-day, others in the Botany. sometimes happens that, in place of producing flowers, they develop branches and leaves luxuriantly. In these instances cutting the roots, pruning the branches, taking a ring of bark out of the stem so as to retard the descent of sap, and transplanting into poor soil, frequently cause the plants to flower. Injuries inflicted on forest trees late in the season sometimes give rise to autumn flowering. When a branch is grafted on a vigorous stock it often happens that its flowering is accelerated. By this process a check is put to luxuriant branching, and the sap of the old stock stimu-

lates the young graft or scion.

The different periods of the year in the various countries and climates of the globe are marked by the flowering of certain species of plants. Each climate has its peculiar floral calendar. Thus in Scotland we have the Winter Aconite (Eranthis hyemalis) and the Snow-drop (Galanthus nivalis) flowering in February, the Primrose (Primula vulgaris) in March, the Cowslip (Primula veris) and Daffodil (Narcissus Pseudo-Narcissus) in April, the Hawthorn (Cratægus Oxyacantha) in May, numerous successive species expanding their blossoms during each month of summer, the Ivy (Hedera Helix) flowering in September, and the autumn Crocus (Colchicum autumnale) pushing up its flowering-stalks in October. Every month and every week has thus its peculiar flowers. The expansion of certain flowers indicates the revival of vegetation after winter in temperate and cold regions, and after the dry season in warm countries.

The time of expansion of the flowers of the same species in different countries gives indications in regard to the climate; and the difference of seasons in the same locality is also marked by the dates at which the same species flower. The registration of the periodical phenomena of flowering or florescence is suggested by the British Association as one of the points to be attended to in determining the nature of different seasons. In 1829 Schubler states that the Lily of the Valley (Convallaria majalis) flowered at Rome on the 26th April, at Tubingen on 10th May, at Berlin on 17th May, and at Greifswald on 10th June. According to Berghaus the same species flower at Zurich 6 days later than at Parma, at Tubingen 13 days later, at Jena 17, at Berlin 25, at Hamburg 33, at Greifswald 36, and at Christiania 52. The Almond is said to flower at Smyrna early in February, in Germany at the beginning of April, and in Christiania not till the commencement of June. There is thus periodicity in flowering as regards the seasons, and plants retain the tendency to expand their flowers at a definite period of the year even when transported to countries where the seasons are reversed. In these circumstances they do not immediately accommodate themselves to the opposite conditions of the seasons in which they are placed, but for a while continue to show symptoms of flowering at the usual time to which they were accustomed in their native clime. Some varieties flower earlier than others of the same species. This has been noticed in the case of species of Thorn, Horsechestnut, and many other plants. By means of slips taken from such plants gardeners perpetuate early flowering

Temperature is a most important agent in causing plants to flower, but in each species the range of flowering-temperature is definite. A high temperature, in the case of plants belonging to cold regions, often makes them produce leaves in place of flowers, or if flowers are produced, they drop off and are abortive. Fruit trees of temperate regions, when grown in tropical countries, are frequently unproductive. In cultivating plants in hot-houses, it is of importance to regulate the temperature, and at the same time to attend to the state of moisture and ventilation, if we wish the plants to flower properly.

There are differences in regard to the hours of the day at which flowers expand. Some open at dawn of day,

evening, and a few after darkness has come on. Roemeria violacea expands its blossoms early in the morning, and the petals have generally fallen off two or three hours before noon. Many Composite plants, as Chicory (Fig. 375), show a remarkable tendency to open and close their florets. Species of Goat's-beard (Tragopogon) receive the common name of go-to-bed-at-noon on account of closing their florets at mid-day. Ornithogalum umbellatum (Fig. 376) is called Lady-Eleven-o'Clock, on account of its flowers expanding about that hour in the forenoon. CEno-the Cichoraceous plants, the Chicory (Cichorium Inty-bus), which opens its flowers

Fig. 375.

Primrose from opening its flowers in the evening. The vigils of plants attracted the attention of Linnæus, and he constructed what he called a Floral

Clock, in which the hours of the day were indicated by the opening of certain flowers, and which were hence called horological.

Fritzsch has paid particular attention to the opening and closing of flowers, and gives the results of observations made at Prague, in Bohemia. He states that these phenomena are rarely momentary, but that they are slow and continuous processes, which at all hours of

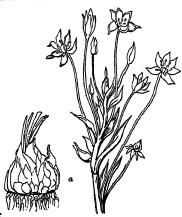

Fig. 376.

flowers in regard to sleeping and waking are influenced by light, by temperature, and more especially by insolation or exposure to the direct rays of the sun. They are also, in a

certain degree, dependent on colour.

Although there seems to be no time of day when the blossoms of certain plants do not open, yet in the greater number of cases they are closed soon after sunset. number of species which begin to awake increases slowly at the early hours of the morning, then more rapidly from 2 A.M. to 7 A.M., and decreases again rapidly after mid-day. After that hour only those species open which are nightbloomers. With the exception of a few hours about midnight there is no hour of the day at which blossoms do not begin to close; there are, however, only a few about midday, from which time the number increases, reaching its maximum at 6, and then again decreasing.

When blossoms begin to open after the cessation of sleep, the change usually takes place in the first instance slowly, then more rapidly, and, as it approaches its maximum there is another retardation. In a few plants only the complete expansion lasts an hour, more commonly not so much; they then begin to close again, at first slowly, afterwards more rapidly, and, as they approach the maximum of approxima-

Botany. tion of their petals, the progress is again slow. The flower remains many hours in a more or less closed condition. until the time returns for a new cycle of phases. The state of expansion of the corolla varies. In some cases the limb spreads out at a right angle with the tube, in other cases the angle is less, while in some the limb is turned down so as to form an oblique angle with the tube.

The time of the greatest expansion of the flowers varies in different species. In general the number of species whose blossoms attain the maximum of their phase increases from sunrise to mid-day, and then decreases till sunset. None of the day-bloomers are open till 7 A.M., or later than 5 P.M. A similar law seems to hold good with the nightbloomers, which generally seem to open their corolla fully towards midnight, while at mid-day they are completely closed. In those blossoms which are fully expanded in the morning, the duration of expansion is short. In those blossoms which expand in the afternoon, the condition of waking is limited by the length of time the sun is above the horizon. In those blossoms which are fully expanded in the night, the duration of sleep is shortest. Those blossoms which are fully expanded in the morning open in general more rapidly than they close, while in those which open in the afternoon the contrary law prevails. While the time of sleep of plants is in close connection with the apparent daily course of the sun, the degree of expansion depends on the temperature of the air and various meteoric conditions, as well as on insolation or exposure to the direct rays of the sun.

Exposure to artificial light causes some flowers to expand. The flowers of Crocus have opened under the light of an Argand lamp, those of Gentiana verna expanded fully when exposed to the light of a gas-burner. Gloomy weather and rain cause flowers to close. Those which are very sensitive to such influences are called meteoric. There is a periodicity in flowering which is not easily interrupted. If a plant is accustomed to flower in daylight at a certain time, it will still make an effort to expand its flowers at the wonted time, even when confined in a dark room; showing that light is not the only cause of the expansion. As regards the connection between the colour of flowers and their expansion, Fritzsch says that vellow blossoms possess the strongest tendency to contract and expand, then follow white, red, and blue.

The direction and position of the flowers on their stalks appear in some cases to be controlled by the sun's rays. This is particularly the case in Composite plants. The capitula of some of them are erect during the day, and droop at night. Species of Hypochæris are said to incline their heads towards the quarter of the heavens in which the sun is shining. The name Sun-flower (Helianthus, Girasole) was given to a genus of Composite plants on account of the supposed influence of the sun on the direction of their heads. In Victoria regia there is a spontaneous motion of the flower and the flower-stalk, the cause of which appears to be very

Occasionally movements of irritability are observed in petals. Morren observed them in the labellum of some Orchids, such as Megaclinium falcatum, and they have been noticed also in the stalk of the labellum of Drakea elastica, which bends in a hinge-like manner when irritated. Various species of Pterostylis, and many Bolbophyllums, especially B. barbigerum and B. Careyanum, show labellar movements. In Caleana nigrita, a Swan River Orchid, the column is a boat-shaped box, the lid of which is formed by the labellum. The latter is hinged on a claw, which reaches the middle of the column; when the flower opens the labellum turns round within the column and falls back, so that, the flower being inverted, it stands fairly over the latter; whenever an insect touches its point the labellum makes a sudden revolution, brings the point to the bottom of the

column, and thus imprisons any insect which the box may contain. If an insect is caught, the labellum remains shut; but if there is no insect, it recovers its position. The labellum of Spiculæa ciliata is also moveable.

Colours of Flowers.—The colours of flowers naturally attract the attention of all, and their varied hues are in an especial manner an object of interest to the florist. These colours usually reside in the corolla, but in the case of many plants, especially Monocotyledons, they occur both in the calyx and corolla (perianth); and in some instances, as in Salvia and Amherstia, the bracts are highly coloured. The changes produced by culture on the colours of many plants are familiar to every one, and they may be well illustrated in the case of the Tulip and Dahlia, the flowers of which are naturally of a yellow colour, but in the hands of the florist assume all varieties of red, white, and yellow. From its variable nature, colour is not taken much into account by the practical botanist in the determination of the species of flowering plants. It is chiefly in Cryptogamic plants, such as Fungi and Seaweeds, that this character is regarded of value. It is probable, however, that too little attention has been paid to this subject, owing to the want of an accurate nomenclature, such as has been adopted by Werner in the characters of minerals.

In reference to their colours, flowers are divided by De Candolle into two series-1. Those having yellow for their type, and which are capable of passing into red and white, and never into blue. 2. Those having blue for their type, and capable of passing into red and white, but never into yellow. The first series is called Xanthic, the second Cyanic. The following is a tabular view of the two series, green being considered as an intermediate state of equilibrium between the two:--

> Orange-red Orange Yellow-orange Yellow Yellow-green Green. Colour of Leaves. Blue-green Blue Blue-violet Violet Violet-red

Green, which is made up of blue and yellow, is the centre whence the two series diverge, and they meet again in red. It would appear that all flowers capable of changing colour do so in general by rising or falling in the series to which they belong.

The original colour of the Tulip is yellow, and although by cultivation it is made to assume all the varieties of colour in the yellow series, we do not find it becoming blue. Such is also the case with the common Dahlia and the Rose. No one has succeeded in getting a blue variety of either of the latter. The Geranium, on the other hand, although it presents all shades of blue, red, and white, does not become yellow. There seems thus to be a certain limit in the range of colour which a species can be made to assume. These remarks apply only to the change of colour in a given They will not apply in all cases to every species species. of a genus. Thus, while most of the Gentians belong to the blue series, and do not become yellow by cultivation, there is a yellow species of the genus (Gentiana lutea) which never changes into blue. Again, we find certain plants exhibiting, in the same flower, blue and yellow colours. This is seen in Dendrobium sanguinolentum; also in Pansies, and in many other parti-coloured flowers, as in Convolvulus tricolor, and in species of Myosotis, which have a yellow zone round the corolline tube, while the upper

Botany. part is blue. In these last mentioned cases each of the coloured portions of the flower vary in general only in their proper series—the part which is yellow never becoming truly blue, nor the blue yellow. The florets of the ray of Composite plants often exhibit blue colours, while those of the disk are yellow. The law by which the changes of colour are regulated has not been ascertained, and it is impossible, in the present state of our knowledge, to predict what colour a florist's flower will assume. The different rays of light have different effects as regards colours. It would appear, also, that the nature of the soil sometimes alters colours. Thus, Hydrangea hortensis (Hortensia speciosa) produces blue in place of pink flowers, when planted in some kinds of bog earth and of yellow loam. The colours of flowers often appear to depend on the state of oxygenation of the juices. Certain flowers have a pale hue when first produced, and change under the influence of sunlight. The colouring matter of flowers is usually of a fluid nature, and has not the composition of chloro-

> The arrangement of coloured flowers in the parterre is a matter deserving the attention of gardeners. Chevreul has written very fully on the subject. He states that an important principle is to combine such colours as produce white light. Thus red, blue, and yellow, form, by their union, a white ray. Hence flowers of these colours may be, with propriety, placed together; or a flower of one of these primary colours may be combined with one whose colour is made up of the other two in the shape of a binary compound. Thus, red agrees well with green, which is made up of yellow and blue. This may be seen in the case of the scarlet Pelargonium, where the colour harmonizes with its own green leaves, or with the green of other plants around it; so also in the case of red Dahlias. Again, blue harmonizes with orange compounded of yellow and red, as may be illustrated by a combination of the Brachycome ıberidifolia with Erysimum Perofskianum. Yellow harmonizes with violet, composed of blue and red, as seen in the petals of Pansies. To produce the best effect the colours should be as nearly as possible of the same tone. In cases where colours do not agree, placing white between them restores the effect.

Odours of Flowers.—The odours of flowers, as well as their colours, vary much. The sources of odours in flowers are very obscure. They are often traced to the presence of fragrant volatile oils or resins. The effluvia are of such a subtle nature as to elude chemical analysis. They are usually developed under the influence of sunshine, but in certain instances odours are emitted during the absence of light. Some flowers are only odoriferous in the evening. This is the case with Cestrum nocturnum, with several species of Catasetum and Cymbidium, and with Lychnis vespertina. Certain flowers, such as Hesperis tristis, and Nyc-

tanthes arbor tristis, receive their specific names (tristis, sad) from giving out their fragrance only at night.

The exudation of odours by nocturnal flowers sometimes takes place in a peculiarly intermittent manner. Thus in the night-blooming Cereus (Cereus grandiflorus) the flowers are fragrant only at intervals, giving out puffs of odour every half hour, from eight in the evening till midnight. Morren states that on one occasion the flower began to expand at six

One of the Carrion flowers (Stape-lia variegata), belonging to the natural order Asolepiadaces. It receives its English name on account of the fetil odour of its dark brown flowers.

Fig. 877.

o'clock in the evening, when the first fragrance was perceptible in the hothouse. A quarter of an hour afterwards the first puff of odour took place, after a rapid motion of the Botanv. calyx; at 6.23 there was another powerful emanation of fragrance; by thirty-five minutes past six the flower was completely open; at a quarter to seven the odour of the calyx was the strongest, but modified by the petals. After this time the emanations of odour took place at the same periods as before. The odours of flowers have frequently peculiar effects on nervous individuals, particularly when the odours are connected with the presence of hydrocyanated oils. The odour of some flowers is remarkably overpowering, and that of others, such as Stapelias or Carrion flowers (Fig. 377), is very offensive.

II.—PHYSIOLOGY OF THE ESSENTIAL ORGANS OF REPRODUCTION.

1. Sexuality of Plants. Maturation of the Organs concerned in Reproduction; and changes preceding the Development of the Embryo.

The idea of the existence of separate sexes in plants was entertained in early times, long before separate male and female organs had been demonstrated. The production of Dates in Egypt, by bringing two kinds of flowers into contact, proves that in very remote periods some notions were entertained on the subject. Female Date Palms only were cultivated, and wild ones were brought from the desert in order to fertilize them. Herodotus informs us that the Babylonians knew of old that there were male and female Date-trees, and that the female required the concurrence of the male to become fertile. This fact was also known to the Egyptians, the Phœnicians, and other nations of Asia and Africa. The Babylonians suspended male clusters from wild Dates over the females; but they seem to have supposed that the fertility thus produced depended on the presence of small flies among the wild flowers, which, by entering the female flowers, caused them to set and ripen. The process was called palmification. A similar statement was made in regard to the Fig. The process of caprification, or bringing wild Figs in contact with cultivated ones, so as to cause the latter to ripen soon, is mentioned by Aristotle, who observed that a certain insect was generated on the flowers of the Caprifig (wild Fig), which, having become a fly, entered the unripe fruit of the domestic Fig. and caused

Grew, in a paper on the Anatomy of Plants, read before the Royal Society in November 1676, seems to have been the first who really observed the functions of the stamens and pistils. Up to this period all was vague conjucture. Grew speaks of the attire, or the stamens, as being the male parts, and he mentions having spoken of the subject to Sir Thomas Millington, Savilian Professor at Oxford, who entertained the same opinion. Ray adopted Grew's views, and states various arguments to prove their correctness in the preface to his work on European Plants, published in 1694. In 1703, Mr Samuel Morland, in a paper read before the Royal Society, stated that the farina (pollen) is a congeries of seminal plants, one of which must be conveyed into every ovum or seed before it can become prolific. In this remarkable statement he seems to anticipate in part the discoveries afterwards made as to pollen tubes, and more particularly the views promulgated by Schleiden. In 1711, Geoffroy, in a memoir presented to the Royal Academy at Paris, supported the views of Grew and others as to the sexes of plants. Linnæus was the next botanical author who took up the subject of the sexes of plants, and he may be said to have opened a new era in the history of Botany. He first published his views in 1736, and divided plants into sexual and asexual, the former being Phanerogamous or flowering, and the latter Cryptogamous or flowerless. In the latter division of plants he could not detect stamens and pistils, and he did not investigate the mode in

Botany. which their germs were produced. He was no physiologist, and did not promulgate any views as to the embryogenic process.

Soon after the promulgation of Linnæus' method of classification, the attention of botanists was directed to the study of Cryptogamic plants, and the valuable work of Hedwig on the reproductive organs of Mosses made its appearance in 1782. He was one of the first to point out the existence of certain cellular bodies in these plants which appeared to perform the functions of reproductive organs, and to them the names of antheridia and pistillidia were given. This opened up a new field of research, and led the way in the study of Cryptogamic reproduction, which has since been much advanced by the labours of numerous botanical inquirers.

In 1815, Treviranus roused the attention of botanists to the development of the embryo, but although he made valuable researches, he did not add much in the way of new information. In 1823, Amici discovered the existence of pollen-tubes, and he was followed by Brongniart and Brown. The latter traced the tubes as far as the nucleus of the ovule. These important discoveries mark a new epoch in Embryology, and may be said to be the foundation of the views now entertained by physiologists, which have been materially aided by the subsequent elucidation of the process of cytogenesis, or cell-development, by Schleiden, Schwann, Mohl, and others. The whole subject has been investigated recently with great assiduity and zeal by physiologists, both as regards Cryptogamous and Phanerogamous plants. formation of germinal vesicles in the ovule, and the development of the embryo in flowering plants, have been fully considered by Schleiden, Mirbel, Mohl, and others; the embryogenic process in Coniferous plants and in the higher Cryptogams by Hofmeister, Suminski, and Mettenius; and that of the lower Cryptogams by Thuret, Decaisne, and Tulasne. We have thus been enabled to come to certain general conclusions on this obscure subject, and future observers have been directed in the proper path of investigation.

In flowering plants the organs concerned in reproduction are the stamens and pistils, while in flowerless plants, organs called antheridia and archegonia, as well as peculiar cells, exist, which appear to perform this function. As regards the former class of plants, many proofs have been given that the pollen discharged from the anthers must be applied to the stigmatic surface of the pistil in order to produce perfect seed. Among the best evidences of the functions of the stamens and pistil in flowering plants, are those derived from species in which these organs are separated, and in which, when contact is carefully prevented, no seed is produced. Experiments of this kind require much caution to avoid fallacy arising from pollen being wafted from a distance, so as to cause female plants to produce fruit. Moreover, it sometimes happens that in plants usually producing pistilliferous flowers only, stamens are developed. Such a case might be considered, by careless observers, as an instance of a female plant producing fertile seed without the action of pollen. When flowers are completely double, that is, when the stamens and pistils are entirely converted into petals, no seed is produced. Occasionally, however, in flowers apparently double, a single stamen may exist, with sufficient pollen to fertilize the plant, or the pistil may be perfect, so that pollen from other plants may affect it, and lead to the production of perfect seed. In certain instances, it has been stated that perfect seed has been produced without the agency of pollen. But the cases require further investigation. Henslow has conjectured that cases where fertile seed is stated to have been formed without the action of pollen, may be analogous to what is seen in Aphides, where one impregnation is sufficient to produce eight or ten generations.

In Phanerogamous plants provision is made for securing VOL. V.

the application of the pollen to the stigmatic portion of the

pistil or to the ovule. The relative lengths of the stamens and pistils, in erect and pendulous flowers, are varied on this account, and the mode in which the anthers open is also made subservient to the same end. In the case of some plants, the elastic filaments are bound down by the floral envelopes until such time as the pollen is ripe, and then they are set free so as to scatter the pollen with great force. This phenomenon is seen in the common Nettle (Urtica dioica), and in the Pellitory of the wall (Fig. 378). In the species of Kalmia a similar phenomenon is ripe, and then the perianth expands, the filaments are thrown out the force, so as to scatter the pollen on the female flowers in the vicinity. floral envelopes until such time as

nomenon is observed, the anthers being held for a time in little pouches or sacs of the corolla, and then moving with a jerk towards the pistil.

In the Barberry (Fig. 379), the filaments are very irritable on their inner surface, at the point where they join

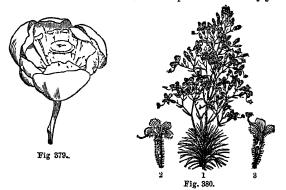

Fig. 379. Flower of the Barberry (Berberis vulgaris), the stamens of which are irritable, and move towards the pisul when touched at their base.

380. A species of Stylewort (Sykudalum tenus johum, which displays irritability in its reproductive column. 1. Plant, with its narrow leaves and numerous flowers, from each of which a column projects formed by the united stamens and pistil. 2. Flower separated, showing callyx, corolla, and column; at the extremity of the latter the anther lobes are placed, surrounding the stigms in the centre. 3. A similar flower, showing the column in the act of passing from one side of the flower to the other.

the receptacle, and when touched in that situation they move towards the central organ. The motion, like that of the leaves of the Sensitive plant, seems to be connected with a small cellular swelling or gland at the base. In species of Stylidium (Fig. 380), the stamens and pistil are united in a common column, which is jointed and irritable, and which, when touched at the joint, passes with force and rapidity from one side of the flower to the opposite one, so as to burst the anthers and scatter the pollen on the central stig-The stamens of the common Rock-rose (Helianthemum vulgare), and of species of Cistus, exhibit movements which are apparently connected with the application of the pollen. In Parnassia palustris (Fig. 381), and in Rue, the stamens move forward in succession towards the pistil.

Insects are sometimes employed in scattering pollen. The bees in collecting the honey secreted at the base of the pe-tals are made instrumental in applying the pollen to the stigma. In Orchids, in which the anthers are placed on the upper part of a column with the stigmatic surface separated from them, and the pollen is in masses (Fig. 265), the agency of insects seem to be required for fertilization. The flowers of these plants exhibit remarkable animal forms, probably with the view of attracting insects. The flowers also secrete a large amount of saccharine matter, and are odoriferous; their pollen-masses are very easily detached. All these circumstances seem to be connected with their mode of impregnation. In Asclepiadaceæ, which have

also peculiar pollinia (Fig. 382), insects are attracted by Botany. the odour of the flowers, which is sometimes very fetid, as

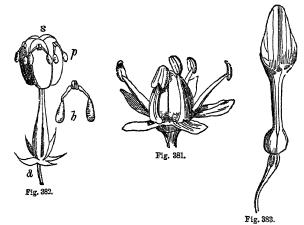

Fig. 331. Flower of the Grass of Parnassus (Parnassia palustis), the stamens of which move in succession towards the pistal, in order to scatter their pollen. In the Figure, some stamens are seen applied to the pistal, and others removed from it.

... 382. Pistal of one of the Asolepiadacese, with the calyx and flower-stalk, a, the pollen masses, p, adhering to the stigma, s. Polken-masses, b, separated with the gland uniting them.

383. Separated with the gland uniting them.

383. Separated with the gland the stamens and pistal at its base. The inside of the tube of the perianth is lined with stiff hairs pointing downwards, which allow the entrance of an insect called Tipula pennicornis, but prevent its exit until the pollen has been scattered on the stigma, and the flower has withered.

in Stapelia (Fig. 377), as well as by saccharine matter. In various species of Birthwort (Fig. 383), in which the essential organs are contained in a tubular perianth, insects are employed to effect the application of the pollen. Species of Tipula enter the expanded portion of the perianth, and then crawl down through the long tube to the cavity at the base containing the stamens and pistil. On attempting to return they are prevented from getting out by numerous hairs pointing downwards, which act like a trap. While moving about in the lower chamber, the insects spread the pollen when ripe, and afterwards when the flower fades they escape.

Pollen grains in general require to be protected from the direct action of moisture, which causes them to burst prematurely. The closing of flowers during rain accomplishes this object. In the Daisy and other Composite plants the outer florets close over the inner ones, and thus prevent injury from wet. When plants grow in water the pollen is sometimes of a peculiar nature, and the anthers are placed along with the pistils in a covering to protect them from the effects of moisture. In other aquatics, the peduncles rise above the water at the time when the flowers are developed. In Vallisneria (Fig. 22), the female plant, b, sends up a long spiral peduncle, which sometimes increases in length 14 inches during twenty-four hours, and which enables the flower to appear above water, and to be accommodated to its depth, at the same time that the root remains attached to the mud below; the male plant, a, on the other hand, is detached from the bottom of the water, floats on the surface, and there perfects its pollen, which is ultimately wafted on the pistilliferous plant.

The fertilizing power of the pollen is retained for a different length of time in different species of plants. According to Kölreuter and Gærtner, the pollen continued fresh in some species of Tobacco only for 48 hours; in Datura Stramonium, D. Tatula, and D. ferox, and in Lychnis dioica for 2 days; in Hibiscus Trionum and the Clove-pink for 3 days; in Lobelia syphilitica and L. splendens for 8 or 9 days; in Wallflower for 14 days; in Orchis abortiva for 2 months. The pollen of the Hemp, Tea, and Camellia, has been kept fresh for a year; and Michaux mentions the pollen of Chamærops humilis and of the Date as having been

used successfully after 18 years. Pollen may be carried to Botany. a distance and retain its fertilizing power.

The quantity of pollen produced in some cases is enormous. In the case of Firs and Pines, this seems to be connected with the fact that the cones or female organs are separate from the staminal clusters, and that, moreover, the leaves are usually evergreen, and thus present an obstacle to fertilization. The yellow powder in Pine forests falls to the ground in vast quantity, and it is sometimes carried by the winds to a great distance, so as to fall in the form of what have been called sulphur showers. Morren counted the number of pollen grains in a plant of Cereus grandiflorus which grew in the stove of the Botanic Garden of Liège. He found that in each flower there were 500 stamens, and as 40 flowers were produced, the total number of stamens on the plant was 20,000, and of pistils 40, each having 24 stigmas. Each anther contained 500 pollen grains, and hence the total number of grains in each flower was 250,000, and upon the entire plant 10,000,000. In many catkinbearing plants, which are monœcious or diœcious, the pollen

common Hazel, and in Willows. Observations have been made by Gærtner and Kölreuter as to the quantity of pollen required to fertilize the ovules. One grain, or at most three, are sufficient to impregnate the ovule of Mirabilis longiflora and M. Jalapa. In a single flower of Hibiscus Trionum, Kölreuter counted 4863 pollen grains, and he ascertained that 50 or 60 were sufficient to fertilize all the ovules in the ovary, usually amounting to 30; when fewer grains were employed, impregnation was not complete; thus 25 grains only impregnated from 10 to 16 ovules. In most cases the pollen of a single fertile anther is sufficient for the perfecting of the ovules, and the additional anthers are produced with the view of insuring the result. Morren states, that in the flower of Cereus grandiflorus he found 150,000 grains of pollen, out of 250,000, which had not been applied to the stigma, while the number of ovules in each ovary was about 30,000.

is abundant, and the essential organs are developed before

the leaves are produced. Examples of this occur in the

During the evolution of the stamens and the maturation of the pollen, the pistil undergoes changes, more especially as regards the stigma, which becomes enlarged, lax in its texture, and covered with a viscid secretion. In species of Campanula, during the discharge of the pollen, the style, which is covered with hairs (Fig. 384), elongates, and in

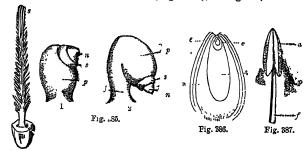

Fig. 384. Style of a species of Bellflower (Campanula) covered with hairs, which collect the pollen.

... 385. The ovule of Celandine (Chelidonium), with its primine, p, secundine, s, and nucleus, n, projecting through the foramen, which is slightly turned round in 1, and completely turned in 2. By this change in the position of the ovule the foramen is brought near the placenta, and the pollen tubes reach it more easily. The funiculus or umbilical cord, f.

... 387. Stamen, s, of Wallflower (Cheiranthus), scattering the pollen, p, from the anther, a. The filament, f.

its upward progress brushes the pollen from the anthers. The hairs which collect the pollen apply it to the stigma, the branches of which, s, are at first erect, and afterwards, by changes in their cells, become revolute. In Goldfussia (Ruellia)

Botany. anisophylla, the style has a curved stigmatic apex, which gradually becomes straightened so as to come into contact with the hairs of the corolla on which the pollen is scattered. The stigma in species of Mimulus, is bilamellar, and the two lamellæ close when touched with pollen or any extraneous body.

> Before the process of impregnation, certain changes also take place in the ovule. The relative position of its parts is frequently altered, so that the micropyle is brought near to the placenta (Fig. 385). Moreover, one of the central cells becomes much enlarged and developed, so as to form the embryo-sac (Fig. 386, s). At the end of this sac, next to the micropyle, several delicate free nucleated cells are produced, to which the name of embryo-vesicles or germinalvesicles has been given (Fig. 386, c). In this way the ovule is prepared for the action of the pollen, and for the production of the embryo plant.

> The essential organs, when performing their active functions, absorb much oxygen and evolve carbonic acid. At the same time they acquire a certain elevation of temperature. This has been already noticed when speaking of the floral envelopes. The time of the emission of pollen seems to be that at which the maximum heat is produced, and the stamens have a higher temperature than the pistil. When the stamens and pistil are mature the anther bursts (Fig. 387), and scatters the pollen, p, on the stigma (Fig. 388, stig). There it is detained, and is acted on by the viscid secretion,

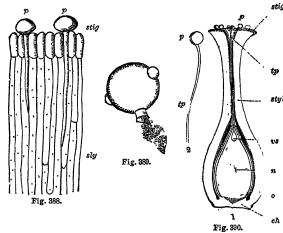

Fig. 398. Grains of Pollen, p. p. applied to the viscid cellular stigma, stig, of Frogsmouth (Antirrhanum majus). The style, sty, is laid open to show the pollen tubes passing down to the ovary.

390. Pistil and pollen of Polygonum. I. Stigma, stig, with pollen grains, p, adherent to it, sending tubes, ty, down the conducting tissue of the style, styl; the ovary, o, containing the ovule with its covering and central cellular mass or nucleus, n, containing a rudimentary embryo-sac, us, in which ultimately the embryo is developed. The base of the ovule attached to the placenta is marked by the chalaza, ch. 2. Follen grain, p, separated, with pollen tube, tp.

by means of which tubes are developed from the intine (Figs. 269, and 390, 2). This is a sort of germination of the pollen cell. These tubes pierce the stigmatic tissue, and convey the fovilla (Fig. 389, f), through the canal of the. style to the ovule. In Figure 390, 1, the ovary, o, with the ovule, n, and embryo-sac, ve, is represented; the pollen, p, is applied to the stigma, stig, and its tubes, tp, pass through the conducting tissue of the style, styl, to reach the embryo-sac.

The emission of tubes sometimes commences half a minute after the pollen has been applied to the stigma; in other cases, as in Mirabilis Jalapa, it takes from 24 to 36 hours. In the Larch Geleznoff says that the tubes do not emerge for 35 days. The length to which the tubes extend is often very great. In Cereus grandiflorus, Morren estimated that the tubes when they reached the ovary ex-

tended as far as 1150 times the diameter of the pollen Botany. grain; in Crinum amabile, Hassall says they reach 1875 times the diameter of the grain, in Cleome speciosa 2719 times, in Oxyanthus speciosus 4489 times, and in Colchicum autumnale 9000 times. The length of time which the pollen tube takes to traverse the conducting tissue of the style varies. The time does not always correspond with the comparative length of the style. In some short-styled plants the time taken is very long, while in the case of the long-styled Cereus grandiflorus and Colchicum autumnale a few hours is sufficient. In the case of some Coniferous plants, as Pinus sylvestris, Pineau states that a year elapses before the tubes reach the embryo-sac.

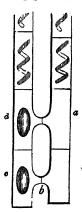

2. Embryogeny in Cryptogamous or Acotyledonous Plants.

In the simplest Cryptogamic plants, composed of a single rounded cell, as in the Red-snow plant (Fig. 56), the processes of reproduction and nutrition cannot be separated. The same cell appears to perform both functions. At a certain period of growth divisions take place in the cell-contents, and, by the bursting of the parent cell, germs are discharged which are capable of producing new individuals. As we ascend in the scale the plants become more complex. In place of one cell they consist of several united together either in a single or branched linear series, and combined both end to end and laterally, so as to form cellular expansions. In this state the nutritive and reproductive cells are often separate and distinct, as may be seen in common Mould, and in Fungi generally. In Confervæ (Fig. 19) and in Diatomaceæ (Fig. 13) the existence of reproductive cells with distinct functions has been observed. In many of them we perceive at certain stages of growth cells united by a process of conjugation, the result of this union being the production of a cellular embryo or spore (Fig. 391, c). This conjugation is a very interesting process, and

tends to throw light on the subject of reproduction throughout the whole vegetable kingdom. The cells in these plants have in their interior a granular endochrome, which appears to have different functions in the different cells. When certain cells are brought into contact, tubes are emitted which unite the two (Fig. 391, b), the endochromes come into contact, and the result is the formation of a spore, the mixed endochromes being surrounded with a proper membrane. Sometimes the contents of one cell considered as the male pass into the other in which the spore is produced, as in Zygnema, and some-times the contents of both cells unite, and the spore is produced in the tube between them, as in Diatoms.

In many of the Confervæ, however, Filaments of Zygnema, spores appear to be produced without the conjugation of separate filaments. In such instances it is conjectured that different cells in the same filament perform different functions, and are so placed that at a certain period their contents by coming into contact develop a germ. The same filament may thus contain both male and female cells; although botanists as yet have cells; although botanists as yet have

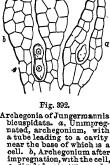

not been able to show the difference between them. In some species of Meloseira the endochrome at each end of the cell appears to have a different property, and mixture takes place in the cavity of a single frustule. In this case there is a movement towards the centre of the cell when the spore is formed.

ferent kinds of reproductive organs, which can, however, only be observed at certain periods of development, and frequently cannot be seen after the embryo has been fully formed. In the same way as in the flowering plants, when the seed has been ripened the stamens have generally withered and fallen off, and sometimes also the style and stigma. It is of importance, therefore, in all investigations into Cryptogamic reproduction, to examine the plants at their early period of growth. The reproductive organs have received different names in different natural orders of Cryptogams. They are generally called antheridia and archegonia or pistillidia, from their supposed analogy to anthers and pistils. The antheridia contain sperm-cells, in each of which is a moving ciliated phytozoon, spirillum, or spermatozoid, and the pistillidium or archegonium contains a germcell or embryonal cell, which produces a germinating body.

Spermatozoids are considered as analogous in their funtion to the spermatozoa of animals. They have been tracec to the archegonia, or the cells in which the rudimentary embryo is formed. Hofmeister states

that he has often seen spermatozoids swimming about around the archegonium, in longitudinal sections of the involucres of Jungermannieæ (Fig. 392); he has also seen them in a motionless state after the rudiment of the fruit began to be developed. Similar observations have been made in regard to Mosses and Ferns; and Suminski is disposed to think that the extremity of a spermatozoid in Ferns is developed as an embryonic cell, in the same way as Schleiden thinks the end of the pollen tube constitutes the first cell of the embryð in flowering plants. Thuret has observed in directious Fuci, that the Archegonia of Jungermannia observed in the archegonium was bicuspidata. a. Unimpregnated. archegonium, with not developed as a germinating body, when the antheridian cells were kept separate. After the application of the contents of the antheridia to the archegonia, a cellular body is produced in the latter, which may be called a sporoid embryo. This cell

may be discharged at once, or it may go through certain phases of existence without being separated from the plant on which it is produced.

In Mosses there is a free germ-cell (embryonal cell) at the base of the archegonium. Spermatozoids, from the sperm-cells of the antheridium, reach it in all probability, and then it is developed into the sporangium or spore-case (Fig. 393), which is the second generation of the plant, according to some authors. The spores produce the leafy plant, bearing antheridia and archegonia. In Figure 394 is shown the confervoid prothallium, p, of a Moss produced from the spore, and bearing buds, a, b, which produce leafy individuals with organs of reproduction. After the contact of these organs, a single cell of the archegonium is developed into the complete fruit (theca or sporangium) which is often borne upon a stalk (Fig. 393). The complete fruit contains spores, which, when discharged, again develop the foliaceous plant. Bruch and Schimper say that Mosses having antheridia and archegonia upon the same stem always bear fruit, and that in dioccious Mosses the capsule is not developed unless the plants bearing sperm-cells and those producing germ-cells are in proximity.

In Ferns the prothallium, pro-embryo, or prothallus (Fig. 395), bears antheridia and archegonia at the same epoch. It is produced from the spore, and consists of cells, as shown

Proceeding to other divisions of Acotyledons, we find dif- in Figure 350. The antheridia occur on the under surface Botany.

This prothallium originates from the spore, and bears a bid, a, and a young stem b, from the base of which roots proceed. This stem bears antheridia and archegonia. An impregnated cell in the archegonium produces the stalked theca or sporangium.

of the prothallium, and they consist of a cellular papills having a central cavity (Fig. 396, α). This cavity contains free cellules, which are discharged by a rupture at the apex, b, and these little cellules, in bursting, give exit to a ciliated spiral filament or spermatozoid (Fig. 397), which swims actively in water. The archegonia (Fig. 398) exist on the under side of the prothallium, near the notch of the border. They are less numerous (varying from three to eight), and consist of cellular papillæ formed by ten or twelve cells. They are larger than the antheridia, and have a central canal, a, leading down to a large globular cell, c (called by some, ovule), imbedded in the substance of the prothallium or pro-embryo, and containing the embryo germ, e. This canal is closed at first, and then opens. In the globular cell at the bottom of the archegonium, a free cell is first formed, which, it is supposed, is reached by the spermatozoids. After a time this cell divides, and is gradually

converted into an embryo, with a bud above and a radicle

Botany. below, from which the regular leafy stem of the Fern grows (Fig. 395, f). The life of the sporangiferous plant is indefinite, as in Tree Ferns, while the prothallium is usually of very short duration. Thus in Ferns the spores contained in the sporangium form the prothallus (Fig. 395, p) without impregnation, and this latter process is necessary for the development of the germ (Fig. 398, e), which gives rise to the leafy sporangiferous stem or frond; while in Mosses the spore forms the prothallus and the leafy stem without impregnation, and this latter operation only causes the development of the stalked theca, or spore-producing part of the plant (Fig. 393)

Hofmeister and Mettenius have examined the reproduction of Club Mosses (Lycopodiaceæ), and have detected antheridia and archegonia. They find that the small spores of Lycopods discharged from the antheridia (Fig. 358), do not produce new plants, but have an office analogous to that of the pollen, namely, to effect the fertilization of a germ produced by the large spore (Fig. 359). The small spores contain cellules with spiral filaments or spermatozoids (Fig. 399, c); the other spore emitted from the oophoridium or sporangium is much larger than the pollinic spore, and is the

analogue of the ovule. The large spore forms a cellular prothallium in its interior (Fig. 400, p), on which archegonia are developed. The process of impregnation is supposed to take place here by the spermatozoids of the small

spores coming into contact with the large spore, after the coat of the large spore has burst at its apex, so as to expose the cellular prothallium and its archegonia. The free cengrows down into the prothallium (Fig. 401). A suspensor is thus formed, at the end of which is the embryo, e,

imbedded in the cellular tissue at the upper part of the large The embryo finally produces its radicle and its bud, which is developed as the leafy frond. In Rhizocarps the antheridia are sacs containing small spores, which emit cellules with spermatozoids (Fig. 402). The large spores contained in the sporangia of Rhizocarps produce a prothallium like that of Lycopods, in which archegonia appear (Fig. 403). The prothallium usually develops only one central archegonium. To this the spermatozoids get access, and then the development of the embryo takes

Embryogeny in Gymnospermous Phanerogams.

In Gymnospermous plants, such as Coniferæ and Cycadaceæ,* impregnation is effected by direct contact between *Plate the pollen and the ovule. There is no true ovary bearing CXXXIV. a stigma. In the Coniferæ the scales covering the seeds are either reckoned as bracts or as expanded ovarian leaves. In Cycadaceæ the naked ovules are produced on the margin of modified leaves. In both these orders it is usual to meet with more than one embryo in the perfect seed. In the Coniferæ there is also a peculiar delay in the production of the embryo, after the contact of the pollen. The phases through which the embryo passes in the seed may be reckoned as somewhat similar to those observed in the case of Lycopodium. Brown long ago noticed in the albumen of Coniferous seeds semicylindrical bodies, three to six in number, which he called corpuscles and which are produced before the pollen tube reaches the ovular sac (Fig. 406, d). They are arranged in a circle near the apex, and differ from the mass of the albumen in colour as well as consistence.

Hofmeister gives the following views as to the production of the embryo in Gymnosperms. The ovule of Conifers consists of a short nucleus inclosed in a single integument, and having a large micropyle (Fig. 404). In the delicate cellular nucleus there is developed an embryo-sac, b, sometimes more than one, as in the Yew tribe. The pollen grains enter the large micropyle and come into contact with the nucleus, and then send their tubes into its apex (Fig. 405, This process sometimes requires several weeks or months. After this the embryo-sac (Fig. 405 b) becomes gradually filled with cellular tissue or endosperm cells, and at the same time enlarges. This development of endosperm cells occupies frequently a long time, especially in the

Vertical section of the ovule of the Austrian Pine (Pinus austriaca), showing the nucleus, a, consisting of delocate cellular tissue containing deep in its substance an embryo-sac, b, formed before impregnation by the coalescence of a vertical series of a few cells. The micropyle, m, is very wide, and through it the pollen grains come into contact with the summit of the nucleus, into the substance of which they send their tubes.

105. Vertical section of the ovule of the Soctoh Fir (Pinus sylvestris) in May of the second year, showing the enlarged embryo-sac, b, full of endopermal cells, and pollen tubes, c, penetrating the summit of the nucleus after the pollen has entered the large micropyle of the ovule.

nucleus after the pollen has entered the large micropyle of the ovule.

... 406. Vertical section of the embryo-sac, b, and of part of the nucleus, a, of the ovule of the Weymouth Pine (Pinus Strobus). At the micropylar end of the embryo-sac, two cells called corpuscles, d, have made their appearance. Each of these is at first separated from the inner surface of the micropylar end of the sac by a single cell, which afterwards divides into four, leaving a passage from the surface of the sac down to the corpuscle. The pollen grain, c, on the summit of the nucleus, then sends down a tube which perforates the embryo-sac, and reaches the corpuscle through the intercellular canal.

... 407. Nucleated cells of what Hofmeister calls the pro-embryo, in the ovule of the Weymouth Pine (Pinus Strobus). The cells are pushed downwards into the cellular tissue of the nucleus by the elongation of the upper cells, which finally form the suspensor.

Abietineæ, which require two years to ripen their seeds. After the embryo-sac has become filled with cellular tissue, certain cells at the micropylar end of the sac enlarge and form the corpuscles of Brown, the secondary embryo-sacs of Mirble and Spach (Fig. 406, d). Each corpuscle is at first separated from the inner surface of the embryo-sac by a simple cell, which afterwards divides into four by the formation of two vertical septa crossing each other; then a passage is formed between the inner angles of these cells leading to the corpuscle. In the cavity of each corpuscle free cells appear. After the corpuscles become evident,

the pollen tubes resume their growth, pass through the tissue of the nucleus, and reach the outside of the embryo-sac, one over each corpuscle. The tubes then perforate the membrane of the embryo-sac, reach the canal between the four cells, and come into contact with the corpuscle (Fig. 406, d). A cell at the lower end of the corpuscle then enlarges, and forms the embryonal vesicle. A free cell in the vesicle divides into eight cells by vertical and transverse septa, and these together constitute a short cylindrical cellular body (Fig. 407), the pro-embryo, as it is called by Hofmeister. The four lower cells of this pro-embryo, by

the elongation of the upper ones (Fig. 408), are finally pushed into the substance of the nucleus. The four elongated pro-embryonic cells (Fig. 409, 1) now appear as isolated suspensors (Fig. 409, 2), and the cell at the end of each suspensor becomes an embryo, g. There are thus four times as many rudimentary embryos as there are corpuscles. Usually one of

corpuscles. Usually one of these only becomes developed as the embryo of the ripe seed.

The view which seems to be supported by the best physiologists is thus given by Henfrey. In Conifers and Cycads, which embrace Gymnospermous plants, the pollen grains are applied to the micropyle of the ovule, without the intervention of a stigma; they then traverse the cells of the nucleus, and reach the embryo-sac. of the nucleus, and reach the its extremity.

embryo-sac. The endospermal cells which fill this sac develop corpuscles consisting of an enlarged cell surmounted by four others, which leave a canal between them leading to the large cell. The pollen tube enters the canal between these cells, and impregnates the large cell of each corpuscle, just as the spermatozoid acts in the case of Ferns. large central cell then produces four suspensors, each of which presents at its extremity a rudimentary embryo, only one of which becomes fully developed.

Embryogeny in Angiospermous Phanerogams.

In regard to Phanerogamous Angiosperms, when the pollen grains are discharged from the anther, they are applied to the stigmatic surface of the pistil, and the viscid fluid there secreted causes a rupture of the extine and the protrusion of the intine in the form of a tubular prolongation (Fig. 269, t), which gradually elongates as it proceeds down the loose conducting tissue of the style. The closed extremity of the pollinic tube sooner or later comes into contact with the ovule, and, in some cases, it appears to be met by a tubular prolongation from the ovule itself. When the pollen tube reaches the ovule it proceeds through the foramen or micropyle so as to come into contact with the embryo-sac (Fig. 386, s). Consequent on this is the development of the cellular embryo. The determination, however, of the steps of the embryogenic process has given rise to disputes among physiologists. Schleiden maintains that the end of the pollen tube enters or introverts the embryo-sac, and becomes the rudimental cell of the embryo, while most physiologists think that the tube merely comes into contact with the sac, in which a germinal vesicle has been previously formed ready for impregnation. Schleiden states that a cell of the nucleus is developed into the embryo-sac (the quintine of Mirbel), seen in Figure 410, s, and that this occurs in all Phanero-

gamous plants; that the embryo-sac contains a substance Botany. which is gradually transformed into cellular tissue, and which ultimately constitutes (when not absorbed by the growth of the embryo) the endosperm or albumen; that the pollen tube can be traced from the stigma to the micropyle in a very large number of plants, and that in Helianthemum dentatum he has not unfrequently extracted the pollen tube free, in unbroken continuity, from the pollen , grain to the ovule; that the tube next reaches the embryo-sac, s, the walls of which it presses in before it, and thus becomes surrounded by it, although in reality external to it, like the intestines and their peritoneal covering; that in some instances it causes absorption of the walls of the sac and enters it, and that the end of the pollen tube, e, forms the rudiment of the embryo or the germinal vesicle, in which cells are developed from cytoblasts, while a portion of variable length, at the upper part of the tube, remains as the suspensor or embryophore.

The views of Schleiden, when first propounded, stimulated all vegetable

propounded, stimulated all vegetable

physiologists. The facts were new, and seemed to upset all former ideas as to the nature of the stamens and pistils. Mirbel and Spach, Meyen, Amici, Hofmeister, Müller, Tulasne, and others, entered the field, and the result has been that Schleiden's opinions have not been confirmed. These authors agree in tracing the pollen tube downwards to the ovule, and they maintain that in the embryo-sac there exists one or more vesicles before impregnation, and that one of these vesicles, after the impact of the pollen tube with the embryo-sac, becomes altered and enlarged, so as to form the rudiment of the embryo.

Amici maintains that there exists an embryonic or germinal vesicle before the application of the pollen; that the pollen tube (Fig. 411, t) reaches the upper portion of the

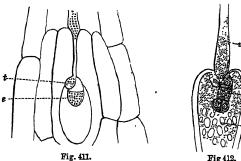

Fig 412. Fig. 411. Section of ovule of an Orchis (Orchis Morio), showing the pollen tube passing through the endostome, and reaching the embryo-sao in the nucleus. The closed and enlarged end of the tube, t, is applied to the sac, in which a vesicle had been previously formed. Transudation of fluids takes place, and the embryo, e, is developed at the lower end of the germinal or embryonal vesicle, while the upper part of the vesicle elongates, and forms a confervoid suspensor.

at the lower end of the germina.

upper part of the vesicle clongates, and forms a confervoid suspensor.

Bctany.

Botany. the elongation of the upper part in the form of a confervoid filament, which acts as a suspensor of the embryo. Hofmeister has examined the mode of fecundation in species of Œnothera, Godetia, and Boisduvalia, and the result of his researches is that he finds an embryo-sac containing at first numerous minute granules floating in a viscid mucilaginous fluid (protoplasm); in the midst of this granular matter certain nuclei appear, which develop cells varying in number from one to three or more (Fig. 412, v). These nucleated cells appear before impregnation; one of them becomes pyriform, and touches the membrane of the embryo-sac by its conical extremity, while its other extremity hangs free in This cell is the germinal vesicle—the the embryo-sac. embryonary vesicle of Amici. The pollen tube, in passing through the micropyle, is often contracted in its diameter. The end of it is expanded when it reaches the embryo-sac, to which it is applied either at the apex or near it (Fig 412, t). Sometimes the end of the tube, still closed, introverts the sac, as seen in the Figure, or even perforates it, so as to come into contact with the germinal vesicle. In either case an endosmotic action takes place between the contents of the tube and the sac or the vesicle. In consequence of this action, cell-formation begins in one, rarely more germinal vesicles. The vesicle increases, and is transformed into a compound cellular mass, which Hofmeister calls the proembryo. This divides into two by the formation of a septum; the upper part elongates, and forms a septate cellular suspensor, s, while the lower portion becomes globular, divides into four, and is developed as the embryo, surrounded by endospermal cells, e. Similar observations have been made by Mohl, Tulasne, Henfrey, and others.

The following may be given as a Resumé of the facts ascertained relative to the process of impregnation in Angiospermous Flowering plants. The pollen grains are applied to the stigmatic portion of the pistil, and by the action of the viscid secretion of the stigma a sort of germination commences—often in a few minutes, sometimes not for many hours, by means of which minute tubes are developed from the inner lining of the grains. These tubes, by continuous growth at their ends, are elongated, and pass through the conducting tissue of the style into the ovary-attaining, in some long-styled plants, a length exceeding the diameter of the grain many thousand times. Before the tubes reach the ovary the ovules have undergone changes in their interior; the embryo-sac has become enlarged, so as sometimes to occupy nearly the entire nucleus, and occasionally to project out of the micropyle in the form of an ovular tube or bag. The protoplasmic matter contained in the embryo-sac immediately before impregnation becomes altered, so as to produce endospermal cells. Nuclei appear in the protoplasm at the upper end of the sac next the micropyle. These nuclei, which are usually three, give origin to as many cells, which are termed the germinal or embryonal vesicles, and which are essential for the formation of the embryo. pollen tube, subsequent to this, reaches the upper part of the embryo-sac, after penetrating through the micropyle and any nuclear cells that may lie between it and the sac.

On reaching the embryo-sac the pollen tube is either arrested or it elongates still more, so that its swollen extremity penetrates latterly between the embryo-sac and the surrounding cellular tissue, or in certain rare instances introverts the embryo-sac, and even penetrates it so as to come into contact with the germinal vesicles. When the end of the tube comes into contact with the sac, it is probable that there is a transudation of the fluid matter of the fovilla, which passes through the membrane of the pollen tube, through the embryo-sac, and through the wall of the germinal vesicle, and thus impregnation is effected. After reaching the sac, the pollen tube begins to decay; its contents acquire a granular, half-coagulated aspect; and it' finally disappears by absorption. It usually happens that

only one germinal vesicle is impregnated, and in the progress of its subsequent growth it causes absorption of the others; sometimes, however, several are impregnated, and thus there may be a plurality of embryos formed (polyembryony). The impregnated vesicle enlarges, acquires an ovate, cylindrical, or clavate form, constituting the pro-embryo of Hofmeister. The vesicle divides in all cases by a transverse partition into two cells, one above the other; the lower of these produces cellular tissue in its interior, and is sometimes at once transformed into the embryo. At other times, and more frequently, there is a successive production of cells in the pro-embryonic body, so that the upper division of the vesicle forms a confervoid-like filament, the suspensor, while the lower is transformed into a globular cellular mass, which is the rudiment of the embryo. The suspensor is sometimes of great length; it is attached to the radicular end of the embryo, while the cotyledons are formed at the opposite side. In monocotyledons a single sheathing cotyledon is developed; in dicotyledons two opposite leaves, and after their formation the apex produces the terminal bud or plumule. The embryo is thus suspended in an inverted manner in the seed. In the progress of development a marked division takes place between the radicular extremity and the suspensor, and the latter finally shrivels.

5. Hybridization, or the production of Hybrids in Plants.

In connection with the subject of fertilization, the production of hybrids or mules deserves attention. When the pollen of one species is applied to the stigma of another species, so as to effect fecundation, the seeds thus formed give rise to individuals which are intermediate in their characters between the two parents. The plants produced by this heterogeneous fertilization are called hybrids or mules. A true hybrid is a cross between two species, but the term is often applied to crosses between mere varieties, races, or sub-species. The latter sort of crosses have been occasionally denominated sub-hybrids in order to avoid confusion. In hybridizing it is necessary to bring together species which are allied, as, for instance, the species of the same genus, or those of allied genera. It is not, however, easy to determine the plants which can produce hybrids. Many plants which seem to be nearly allied do not inoculate each other. Sageret failed in his endeavours to fecundate an apple tree by a pear tree, and no one has succeeded in getting hybrids between the gooseberry and currant, nor between the strawberry and raspberry. It is not common to meet with hybrids in a wild state, because there is a much greater likelihood of the pistil being impregnated by the pollen of the anthers beside it, than by that from a distance; and if fecundation has taken place, then pollen applied from other sources has

It has been found that for successful hybridizing the pollen must be in perfection, and the stigma also must be fully developed. There appears always to be a preference for its own pollen on the part of the stigma. When strange pollen is applied, even in the case of species which hybridize, it does not act so effectually on the ovules as the pollen belonging to the flower. Dichogamous plants, that is, those in which the sexes are separate, are not so susceptible of the influence of strange pollen. This seems to be a provision to guard against hybridity in such cases.

When impregnation takes place between two pure species the characters of the parents never remain pure and unaltered in the formation of the hybrid. In general every part of the new production is modified, so that it presents a decided difference from either of the parents, though resembling the one more than the other. Sometimes the influence of the male predominates, sometimes that of the female. Hybrids occur in which the characters of the parents are intimately blended, so that it is impossible to say

Botany. to which there is a greater resemblance. Sometimes the number of the organs is curiously intermediate; thus Cucubalus has three stigmas, and Lychnis five, and a hybrid between them has four. Again, hybrids occur in which one part or other approaches the paternal or maternal form, though the characters of the parent never pass altogether pure into the new organism. There is a third set of hybrids in which there is a resemblance to one of the parents, whether male or female, so decided, that the agreement is at once perceptible and beyond doubt.

Hybrids, although they may be fertile at first, rarely continue so for many generations. The cause of sterility in mules has not been fully ascertained. Henslow could not find in a hybrid Digitalis any structural changes which could account for barrenness. Hybrids may be fertilized by pollen taken from one of the parents, and then the offspring approaches in character to that parent. Hybrids impregnated for a third or fourth time with the pollen of the original male plant, approach more and more to the male type. Such is also the case when the impregnation is effected by pollen taken from the original female type, but in this instance the change is usually more slow. Gærtner, to whom we are indebted for most of these remarks on hybridity, gives a tabular view of the number of impregnations requisite to complete changes of species by hybridization. He produced hybrids between the two species named, and then, by using the pollen of the original male or female parent, he found that in progress of time the species are

brought back to the male or female type.

Hybridizing is an important horticultural operation. By it the gardener endeavours to increase the size of flowers, to improve their colour, to approximate their forms to some assumed standard of perfection, to enlarge the foliage as in esculents, to render tender plants hardy, to heighten the flavour of fruits, and to exchange early for late varieties. The changes produced by muling on the size and colour of the blossoms are very remarkable. By inoculating Cereus speciosissimus with C. grandiflorus, we find that the immediate result is a seedling whose flowers are ten inches in diameter. The hues resulting, however, from the union are not necessarily intermediate. Blue and yellow do not produce green, as proved by a hybrid between Verbascum phæniceum and V. phlomoides. By muling, beautiful varieties have been produced between Rosa indica and R. moschata, Azalea pontica and A. nudiflora coccinea, Rhododendron arboreum and R. caucasicum, catawbiense, ponticum and companulatum; between Rhodothamnus Chamæcistus and Phyllodoce cærulea, Veronica fruticulosa and saxatilis, Cereus speciosus and speciosissimus; also between species of Fuchsia, Mahonia, Potentilla, Pelargonium, Calceolaria, Viola, Dahlia, Erica, Narcissus, and numerous others. In the case of Rhododendrons, gardeners have been able to secure the fine colour of the Indian R. arboreum with the hardiness of the American species. By inoculating the common Heartsease with the large-flowered Pansy of the Altai Mountains, a degree of vigour has been infused into the former which we could not hope to obtain by ordinary means. The fine varieties of Pelargonium have been obtained, by cultivation and by hybridizing, from the smallpetaled Pelargonium of the Cape. Fruits and culinary vegetables are sometimes improved by hybridity. These hybrids cannot be continued from seed. They must be propagated by offsets or cuttings. The effect of hybridizing or crossing is very marked in the case of certain Cereal plants.

This subject has important bearings on the origin and limitation of species. If, as some old authors supposed, there were only a few species originally formed, and all the rest are the result of hybridization, there would be no limit to the production of species, and no permanence in their characters. This opinion, however, is not supported by facts. It is believed that the types of all the species now on the

globe were originally placed on it, and have given origin to Botany. offspring like themselves, capable of reproducing the species. We have already mentioned that hybrids are rare in a wild state, and they are seldom permanent and fertile, and they have always a tendency to revert to one of the original

III .- PHYSIOLOGY OF THE FRUIT.

While the object of fecundation is to develop the embryo in the seed, it causes at the same time changes in the pistil The stigma and style become dry, and either fall off, as in the Peach, Orange, and Nut, or are persistent, as in the Poppy (Fig. 309), Mangosteen, Clematis, and in many pods. (Fig. 314). The pericarp in some instances becomes swollen, even although the ovule is not fecundated. In such cases the fruit is abortive in as far as reproduction is concerned, although it may be valued for domestic purposes. Many of the best Oranges and Grapes contain no perfect seeds, and the fruit of the Banana, Plantain, Bread-fruit, and Pineapple, is most palatable when it is seedless. The age of trees seems to have an influence over the production of seeds. In the case of the Orange, it is said by Bullar that old trees

often produce seedless fruit.

The fruit during its growth attracts nourishment from the surrounding parts, and it is of importance that it should receive a large supply of elaborated sap. In their natural state some plants exhaust themselves in the production of fruit, and die after one year, if annuals, or after two, if biennials. Sometimes fruiting is long delayed, and ultimately takes place vigorously and abundantly. This is observed in plants such as the American Aloe, which only fruits once after many years, and then dies. The division of plants into Monocarpic (μόνος, one, and καρπός, fruit) and Polycarpic (πολύς, many) is founded on their times of flowering and fruiting. The former are such as flower and fruit only once in their life and then die; and this may take place at the end of one year, two years, or many years. The latter are such as flower and fruit many times in the course of their lives. A plant which has been prevented by an inclement season from perfecting its fruit, will often bear a large quantity the following season, if genial. An annual, by being prevented from fruiting, may be made to endure for two or more years. The increased vigour of perennials enables them to withstand the exhaustion induced by fruiting.

In the case of cultivated plants, where the object of the gardener is to have a supply of good fruit, many artificial means have been adopted to promote the development and maturation of the pericarp. The application of manure to the soil, by increasing the vigour of the plants, aids in this matter; also checking the branches by judicious pruning, so as to cause a great flow of sap to the fruit; and cutting a ring of bark from the branches, so as to produce accumula-tion of sap above the wound. In ringing the bark, care must be taken to make the cut so that the two lips of the wound may reunite in the course of a few months. If the cut is large, then the branch may be destroyed. It is prudent not to ring the bark of the main stem, but only that of branches; and the wound should be covered with graftingclay and damp moss, so as to allow the healing process to go on. Checking the roots has an important influence on the production of fruit. When fruit sets in large quantity, it is prudent to thin it early, and thus allow only a moderate quantity to come to perfection. As the sap is distributed to the whole fruit, this operation will permit more nourishment to go to that which remains. By judicious thinning, although the quantity of fruit is diminished, its quality is much improved.

The pericarp sometimes preserves its green colour and leafy aspect, as in the Pea, and continues to act as leaves do, decomposing carbonic acid during daylight, and giving

Botany. out oxygen. Sometimes the cells of the pericarp become I hardened and thickened by the deposit of lignine, and the seed-vessel becomes dry, assuming a white or brown colour. In these circumstances its active vital functions cease, and it no longer produces any marked effect on the air. In other instances the pericarpial cells contain matters which, in the progress of maturation, undergo chemical changes, so that the fruit becomes succulent, and its epicarp assumes various tints of red, yellow, and blue. As transpiration and evaporation take place from the surface of succulent fruits, the fluids in the outer cells become thickened, and thus promote the endosmotic action between them and the cells containing thinner liquids. In this way the fruit swells considerably. When the fruit has attained its full size the stalk dries up, and may be easily detached from the plant; at the same time waxy matter is deposited in the cuticle, which prevents the drying process from going on rapidly.

During their early state pulpy fruits are tasteless or slightly bitter, and they have at that time the structure and chemical constitution of leaves. In their second stage of development they acquire a sour taste from the production of acids, such as malic acid in the Apple and Gooseberry, tartaric acid in the Grape and Tamarind, citric acid in the Lemon, Orange, Red Currant, and Cranberry. In the third stage, or that of ripening, the acids diminish in quantity, they are more fully neutralized by the alkalies present in the fruit, and are partially decomposed; the cellulose forming the walls of the cells and vessels is also transformed, and along with the gum is converted into grape sugar. Saccharine matter may be formed from the acids in the fruit, by the addition of the elements of water, and the separation of oxygen. The changes which take place during ripening consist chiefly in a diminution of the quantity of water and of ligneous matter, and an increase in the quantity of sugar. Saussure and Couverchel state that ripe

Grapes, Apples, and Pears, when separated from their re-

spective plants, and kept at a temperature of about 60° Fahr.

gave out carbonic acid.

Berard thinks that these changes in fruits depend essentially on the action of the oxygen of the air. Fleshy fruits, he says, may be preserved with little alteration for many weeks in vacuo, in nitrogen, and in hydrogen gas; Peaches, Plums, and Apricots, may be kept from twenty to thirty days, and Pears and Apples for three months, in a sealed bottle, containing a little sulphate of iron, lime, and water, which remove the oxygen of the air. Fremy found that the ripening of the fruit was arrested by covering it with varnish, which he supposes to act partly by preventing the access of air, and partly by stopping the transpiration, and thus checking the flow of sap into the fruit. Couverchel says that the sugar of fruits is formed by the action of organic acids on the gum, dextrin, and starch; while others think that the cellulose and lignine are also transformed into sugar by the action of acids.

Certain fruits, more especially those belonging to the natural orders Pomaceæ and Ebenaceæ, after being ripe, undergo a series of chemical changes when pulled and allowed to remain in a room at a moderate temperature. The austerity of Medlars is diminished under this process, to which the name of bletting (French, blette) is given by Lindley. It is a stage intervening between what is commonly called ripeness and decay. The chemical changes consist in a loss of weight, in consequence of a separation of water and a diminution in the quantity of saccharine and ligneous matter. There is a slight increase at the same time in the albuminous matter and in the malic acid. During the maturation of certain fruits, oily and aromatic substances are produced which give a peculiar flavour. In fruits which form jellies, there is developed a gelatinous matter, to which the name of Pectic acid is given.

The greater number of plants ripen their fruit consider-

ably within a year from the time when the flower expands, and some require only a few days for the purpose. Some trees, as certain species of Oak, require eighteen months: Juniper fruit, and cones of the Firs, the fruit of some American Oaks, and of the Metrosideros of New Holland, hang above twelve months; and the Cedar requires twenty-seven months to mature its fruit or to bring its seeds to perfection. The Orange presents a singular phenomenon in respect to maturation of its fruit. This is generally looked upon as ripe at the end of the first year; but it often happens in the south of Europe that, in order to obtain Oranges of the best quality, the fruit is allowed to remain for a second summer on the tree. It is not easy then to say what is the real term of maturation in this fruit in its natural state. Discussions have arisen as to the time when the fruit of the cereal plants is most productive to the farmer. Many think that wheat ought to be cut before the fruit reaches perfect maturity, inasmuch as it then yields most flour. When allowed to remain till fully ripe, then the outer covering or bran thickens at the expense of the flour. Such is also said to be the case in Oats. About a fortnight before ripening is said to be the proper time for cutting corn, as the skin is then thinner, the grain fuller, the bushel heavier, and the yield of flour greater.

The period in which fruits ripen is materially accelerated by an increase of temperature, and their flavour is also improved. Hence the use of putting fruit under glass, or on slates of a dark colour, or wrapping it up in thin bags. The maturation is also accelerated by removing a ring of bark from the branch or stem, which leads to an accumulation of descending sap above the cut. When fruit trees belonging to a cold climate are transferred to a hot one, it frequently happens that no fruit is produced; the leaves become luxuriant, and the flowers, if they expand, are abortive. A high temperature sometimes seems to cause the production of unisexual male flowers only. Hence plants in hothouses when over stimulated by continued heat, are often abortive. They require a season of rest or repose in order to perform their functions properly.

IV .- PHYSIOLOGY OF THE SEED.

1. Muturation of the Seed, and Modes in which Seeds are scattered and deposited in the Soil.

The production of an embryo is the object of fertilization. In the case of flowering plants this embryo is contained in the seed, in which it attains a certain degree of development. In these plants after impregnation the ovule undergoes evident changes. The embryo plant enlarges, attracts nourishment from the surrounding tissues, and either absorbs all the contents of the ovule, or becomes surrounded by a store of perisperm (albumen) which is deposited within or on the outside of the embryo-sac, or in both situations. The nucleus of the ovule is either absorbed or becomes filled with various azotized and unazotized matters, while the coats (especially the outer one) become denser and firmer, and the foramen is closed. Lignine is often deposited on the walls of the cells of the episperm. The seed by means of these changes is rendered more fit to resist vicissitudes of temperature and other accidents which might injure the vitality of the embryo.

An aperispermic embryo (Fig. 334) has all the nutriment contained in its own substance, especially in its cotyledons, and when the coats of the seed are removed the embryo alone is found within. A perispermic embryo has a separate store of nutriment beside it, and when the seed-coats are taken off the embryo is found surrounded more or less completely by this nutritive matter or perisperm (Fig. 335). The perisperm consists of amylaceous, gummy, and saccharine matters, with oils, resins, nitrogenous substances, and

certain salts, such as phosphates, sulphates, and chlorides. The presence or absence of perisperm seems to be connected with the mode in which the seed germinates, and the nature of the perisperm varies according as the seeds sprout rapidly or lie long dormant in the soil. The store of nourishment laid up in the seed is greater than the embryo requires in ordinary circumstances. When the perisperm is not allowed to be fully formed before the seed is detached from the plant, it sometimes happens that owing to the soft and succulent condition of the albumen, the embryo sprouts rapidly. In such cases, however, the embryo does not germinate vigorously, and is apt to fail from want of a due supply of nutriment. Some seeds continue to be of a soft texture, while others assume a stony hardness, as is the case in the Date, and in the Ivory Palm. Some ripe seeds are of greater specific gravity than water, and sink when thrown on it. In other instances, especially when air is contained in the envelopes, as in the Indian Cress, the seeds float in water.

When the seed is ripe, it is either discharged from the seed-vessel, or the fruit remains indehiscent, and falls with the seed still contained in it. Fleshy fruits, such as Apples and Peaches, fall from the tree when ripe, and their succulent portion serves as nutriment for the young embryo while sprouting. Many dry fruits, especially such as are monospermal, (Fig. 317) fall along with the seed which they inclose. In the cereal grains the pericarpial covering and the integument of the seeds are incorporated, and in the fruit of Labiatæ and Boraginaceæ these two coverings continue attached when the seed is ripe. In Compositæ (Fig. 206) and Valerian the hairy calvx remains attached to the fruit, so as to be the means of dispersing it along with the contained seed, and in samaroid fruits (Fig. 322) there are winged appendages for the same purpose. In the case of the Dandelion (Fig. 155), the receptacle, which is at first succulent and flattened, becomes dry and convex, and the phyllaries, which are erect, become deflexed, so as to allow the fruit to be easily scattered. Other dry fruits dehisce in various ways, as already mentioned, so as to scatter the seeds. The opening of the seed-vessels takes place either as the result of a drying process, as in Mahogany, or from the effects of moisture, as in species of Mesembryanthemum, and in the pod of Anastatica hierochuntina, commonly called the Rose of Jericho. Some plants are called Hypocarpogean (ὑπὸ, under, καρπὸς, fruit, and γέα, earth), because their fruit is subterranean—that is, it is either produced on peduncles underground, or, after being ripened in the air, is pushed into the soil by a curvation of the fruit-stalk. Vicia amphicarpos and Lathyrus setifolius var. amphicarpos produce fruit both on aerial and subterranean branches. Arachis hypogæa, called Earth-nut, produces on its aerial branches abortive flowers, while on those underground it develops perfect pods. The peduncle of Linaria Cymbalaria at the time of flowering is straight and short, but it afterwards elongates and curves irregularly, until it comes to a fissure in the rock or wall on which it grows; there it inserts the capsule, which subsequently allows the seeds to escape. The extremity of the peduncle of Trifolium subterraneum is provided with a hard point, by means of which, after its curvation, it penetrates the soil and deposits its pods.

Seeds are sometimes provided with hairy and winged appendages, as seen in the case of Cotton, Willow, Asclepias (Fig. 329), Pine (Fig. 328), Mahogany, and Bignonia, for the purpose of being wafted to a distance by the agency of winds. The seeds of plants valuable as food have been dispersed by man over various quarters of the globe. Streams also convey to a distance the seeds of plants which grow on their banks. The pulpy covering of some fruits renders them fit for the food of birds and other animals, and when the seeds are hard and inclosed in a stony endocarp, they may escape the action of the gastric juice, and be deposited in a state fit for germination. Seeds are scattered in such a way as to reach

the soil best fitted for their growth, whether the plants are Botany. terrestrial or aquatic.

2. Germination.

Germination (Germinatio, springing), is the term applied to the sprouting of the embryo when placed in circumstances favourable for its growth. In the case of flowerless plants a cell or spore separated from the parent plant is developed into a new organism, while in flowering plants an embryo plant already in a certain stage of development within the seed, begins to send out first its root, and then its cotyledons and primary stem-bud. In the case of the latter class of plants, germination may be defined the act by which the fecundated embryo of a seed leaves the state of torpor in which it has remained for a longer or shorter period, starts into life, as it were, comes out from its envelope, and sustains its existence until such time as the nutritive organs are developed.

Requisites for Germination.—In order that germination may go on, certain conditions are necessary. The most important of these requisites are moisture, a certain temperature, and air. The absence of light is also favourable for the process, and, according to some, electricity promotes it. In general, seeds do not sprout until they are placed in the position which the plants are subsequently to occupy. Occasionally, however, seeds begin to germinate before being detached from the plant, as in the case of the Mangrove tree.

A certain amount of *moisture* is required for germination. If seeds are kept in a dry state they can be preserved for a long time without sprouting. Water is required for the solution of the nutritive matter of the seed, as well as for exciting the endosmotic action of the cells. No circulation nor movement of fluids can take place in the seed until water is taken up. The nourishment of plants is absorbed chiefly in a liquid state. Seeds imbibe a large quantity of water, and in so doing their cells become much distended. By this means they are enabled to burst the hard endocarpial coverings which often surround them, as in the case of what is called stone-fruit.

The amount of heat required for the development of the embryo varies much. Some seeds, as those of plants belonging to coldregions, require a moderate temperature, others belonging to hot countries demand an elevated one. It may be said in general that a temperature varying from 60° to 80° F. is the most favourable for germination. In cold regions the spores of Cryptogams germinate at a very low temperature. In other instances germination proceeds at high temperatures. Dr Hooker states, that on the edges of hot springs in the valley of Soane in India, the temperature of which was sufficient to boil eggs, there occurred sixteen species of flowering plants; he also mentions Ranunculus sceleratus as growing in the vicinity of hot springs near Monghyr in India, at a temperature of 90°.

The necessity of air for germination was demonstrated by Ray, Boyle, and others, before the chemical composition of the atmosphere was discovered. Scheele, Senebier, and Saussure showed that the presence of oxygen gas was required in order to aid in the changes which take place in the seed. When seeds were placed in an atmosphere of hydrogen, nitrogen, and carbonic acid, they did not germinate. When they are buried deeply in the soil, so as to be deprived of the access of air, they do not grow. In such circumstances, when the soil is turned up so as to bring the seeds near the surface, germination often commences. In this way seeds, which have been long dormant, spring up on the embankments of railways, and white Clover frequently appears when the soil is stirred. Some substances which supply oxygen, as weak solutions of chlorate of potass and of oxalic acid, are said to be useful in promoting germination, Chlorine acts in the same way by decomposing water and setting oxygen free.

Seeds germinate more rapidly in *shade* than in light, and in diffuse daylight more quickly than when exposed to the direct solar rays. Experiments have been made as to the effect of different rays on germination. Senebier found that the plants illuminated by the yellow rays grew most rapidly in height; next those in the violet rays; afterwards those in the red; and he concluded that the height and size of a plant was proportionate to the intensity of the illumination, while its verdure depended more on the quality of the rays. Hunt made experiments on the effects of coloured rays on the germination and growth of plants by passing the sun's rays through variously coloured glass. He concluded that the processes of germination and budding are essentially influenced by the chemical principle actinism, transmitted through the blue media; and that while the rays connected with blue light promoted germination, the luminous yellow rays impeded it.

While moisture, heat, air, and darkness, are favourable to germination, it is of importance that these requisites should be properly supplied. In nature seeds are sown in the earth to a moderate depth, so as to be excluded from light, and at the same time to be acted on by air; moisture is supplied by rains and dews, and a certain temperature is given. Such is the plan which we ought to imitate in garden and field operations. In order that seeds when scattered may be placed at a proper depth, the soil must be properly ploughed and pulverized. The preparation of the soil materially promotes germination; when properly ploughed the seeds sink to the same depth throughout the field. The advantage of equal machine-sowing is, that the seeds germinate about the same time, and the crop is also all ripened at once, and the diminution in the quantity of flour caused by allowing some part of it to remain long in a ripe state is avoided. When seed is sown broadcast by the farmer, a certain quantity remains uncovered even after harrowing, and hence it does not germinate freely. This may be one reason why dibbling is more successful as regards the number of seeds which germinate, and why with a smaller expenditure of seed an equal return is made.

The experiments made in regard to the depth at which seeds should be placed, agree in showing the advantage of shallow sowing. The more slightly the seed is covered by the earth, the more rapidly the bud makes its appearance, and the stronger afterwards is the stalk. The deeper the seed lies, the longer the shoot remains before it comes to the surface. Ugazi, from observations made in Bavaria, gives half an inch and one inch as being the best depths at which ordinary cereal grains, as well as Peas, Millet, Maize, Buckwheat, and Lentils, should be sown in argillaceous soils, while two to three inches is the depth proposed in sandy soils.

Draining.—In order that land may be productive in the case of cultivated grains, moisture must be supplied in proper quantity, and a certain amount of heat must be imparted to the soil. This is accomplished by the operation of draining, which has been carried to great perfection of late. Much injury is inflicted on the soil by stagnant water. The land is rendered cold, inasmuch as the sun's rays, in place of being expended in heating the soil, are absorbed by the water, the temperature of which is not raised so rapidly as that of the earth or of the air. There is thus a great loss of heat. Drained land in summer is from 10° to 20° warmer than water-logged land. Moreover, by the exclusion of air there is often an imperfect decay of vegetable and animal matters in the soil, so that acids are produced which are deleterious and hurtful to vegetation. The importance of giving bottom heat to plants cannot be too strongly insisted on.

The object of draining is not so much to get rid of the water, as to make it percolate freely through the whole of the soil, laterally as well as perpendicularly, and thus obtain from it the nutriment, in the shape of ammonia, carbonic

acid, &c., which it contains. As the water disappears, air occupies its place, and hence drained soil is aërated. The effects of draining are both mechanical and chemical. It gives rise to improved efficiency in ploughing, harrowing, and weeding, besides saving seed. It also aids the fertilizing power of manures, ameliorates the climate, raises the temperature of the soil, accelerates the harvest, and improves the herbage and other crops.

The depth of drains, and their distance from each other, must be regulated by the nature of the soil, and of the subsoil. Drains should of course never be shallower than the known depth to which the roots of annuals descend. By making deep, and at the same time efficient drains, we increase the quantity of soil available for the purposes of plants. In the case of deep-rooted plants, it is essential that water should be removed from the lower as well as from the upper portion of the soil. Drains must be kept clear, otherwise their good effects will be lost. Occasionally they become choked up, the roots of plants getting access to them. All that can be done to prevent this, is to make deep drains, and not to allow them to pass near trees; also to keep the land clean.

Vitality of Seeds.—Some seeds must be sown immediately after they are ripe, otherwise they lose their vitality, and decay. This is the case with the seeds of Magnolia, Coffee, Clove, and with those of an oily and mucilaginous nature. Even though the germinating power is lost, the seeds may be in a state fit for food. The seeds of the double Coco-nut (Lodoicea Seychellarum), when carried from the Seychelles Islands to the Maldives, and those of Entada (Pursætha) scandens, when borne by the Gulf-stream from the Antilles to the outer Hebrides, are to all appearance fresh, although they will not sprout when planted. Seeds with very delicate integuments can seldom be kept longer than a few weeks or months, while hard and bony seeds have been known to germinate after the lapse of many years. Certain seeds are known to retain their germinative powers for a long time. The seeds of Cucumber have germinated after seventeen years, those of Colsa and Malva crispa after eighteen, of Althæa rosea after twentythree, Maize after thirty, Haricots or French beans, after thirty-three, Melons after forty-one. For sixty years a bag of seeds supplied the Jardin des Plantes annually with Sensitive plants. Haricots taken from the Herbarium of Tournefort, and which were at least one hundred years old, were found to germinate, as were also seeds of Hieracium, fifty years old, from Fries' Herbarium. Grains of Rye have been found fertile after one hundred and forty years.

Seeds placed in particular circumstances have retained their vitality for a great number of years, and even for centuries. Savi saw for ten years young Tobacco plants continue to spring up in his garden from seed which had been sown naturally. All the young plants were regularly rooted out, and yet the supply continued for the length of time mentioned; showing that many seeds remained dormant, and only appeared as the soil was turned up and exposed to air. Duhamel noticed the re-appearance of Datura Stramonium, after twenty-five years, in a ditch which had been filled up and afterwards cleared. Miller noticed Plantago Psyllium grow in a ditch at Chelsea which had been newly cleared, and where it had never been known to grow in the memory of man. Lindley mentions the germination of Raspberry seeds found in 1834 or 1835 in an ancient barrow (tumulus) near Maiden Castle, along with coins of the Emperor Hadrian. The seeds were found in a coffin thirty feet below the surface, and may have been 1600 to 1700 years old. In Stirlingshire germinative seeds of the Corn Marigold (Chrysanthemum segetum) were found under six or seven feet of peat moss. When new land is turned up it frequently happens that seeds spring up which have lain long dormant. White Clover (Trifolium repens) appears

Botany. in these circumstances. Fumaria micrantha has been known to appear in large quantity on newly stirred ground near Edinburgh. After extensive conflagrations plants often make their appearance which had not been previously seen in the neighbourhood.

It is not easy to account for the manner in which the vitality of many seeds is thus preserved. Uniform temperature, moderate dryness, and exclusion from light and oxygen, appear to be essential requisites. If the temperature is elevated, and moisture and oxygen are present, then germination commences. The vitality of seeds in certain favourable circumstances may thus be preserved for a very extended period, but it is by no means easy to imitate these conditions. The statements made in regard to the preservation of Mummy Wheat have not been confirmed by careful observation. Even in the cases which appeared to be conclusive, fallacies have been detected. Thus Mummy Wheat, supplied by Sir G. Wilkinson to various parties, was found in some cases to contain grains of Maize, a plant of the New World, which leads to the conclusion that in this case the grains had been tampered with. We have no evidence that the Wheat now cultivated as Mummy Wheat was that deposited 3000 years ago in the mummy cases.

Preservation of seeds in a germinating condition is a matter of importance in as far as the introduction of plants from abroad is concerned. Seeds brought from India to Britain round the Cape rarely vegetate freely, while those brought overland succeed well. Seeds are best transported in their pericarps. The flinty coatings of many foreign legumes will preserve the living germ for an indefinite period. In preserving seeds an important requisite is to have them ripe and dry. Such seeds should be put into dry paper, and exposed during transportation to free ventilation in a cool place, as for instance in a coarse bag suspended to a nail in a cabin. Many seeds which cannot be transported when exposed to air, will retain their vital properties if buried in clay. Oily seeds, and those having much tannin in their composition, as Beech-Mast, Acorns, and Nuts, must not only be ripe and dry, but also must be excluded from the air. They are usually put into dry earth or sand pressed hard: or they are preserved in charcoal powder, and enveloped in tin or wax. Exalbuminous seeds, and those having dense and fleshy albumen, bear transportation best. Mr M'Nab has suggested a mode of transmitting seeds by having a strong box about ten inches square, with the sides three quarters of an inch thick, in which alternate layers of earth and seeds are placed, the whole being firmly pressed together. On the arrival of such a box the layers of earth and seeds are taken out in succession and put into separate boxes. Wardian Cases may also be employed for the transmission of seeds in earth. The seeds will thus be brought frequently in a germinating condition.

Alphonse De Candolle finding that there have been fal-lacies in regard to the vitality of seeds, from not attending to the particular circumstances in which they have been preserved, made experiments on the subject by taking seeds of different natural orders, collected simultaneously in the same garden, transported and preserved in the same manner, sown in equal numbers, and in similar conditions of soil, humidity, and temperature. The seeds were collected in the Florence Garden in 1831, and were sown on the 14th May 1846, being nearly 15 years old. He selected 368 species belonging to about 150 different genera, and 53 families. Twenty seeds of each were sown in peat mould in pots, and watered. The pots were kept under examination till autumn. The mean temperature in June, the period when several species sprung up, was 66.2° F, that of July 65.3° F., and the maximum reached 86° and 87.8° F. Out of the 368 species only 17 germinated; of the 17 species which came up, Dolichos unguiculatus was the only one

of 20; others had 1, 2, or 3 germinations in 20 seeds. La- Botany. vatera cretica approached nearest Dolichos, but there were only 6 out of 20 that germinated. Woody species seem to preserve the power of germinating longer than others, whilst biennials are at the opposite extreme. Perennials probably lose the power of germination more quickly than annuals. Large seeds appeared to De Candolle to preserve the power of germinating longer than small ones. The presence or absence of separate albumen did not seem to make any difference. Some albumens, such as those of Coffee and of Umbelliferæ, are difficult to preserve from special chemical Compositæ seem to lose their germinating conditions. power very early. From other experiments, De Candolle concludes, that the duration of the faculty of germination is frequently in an inverse proportion to the power of germinating quickly.

Time required for Germination.—The time required for the germination of seeds depends greatly on the texture of their coats, as well as their age. Some exalbuminous seeds, such as Cresses, which are also very hygroscopic, sprout in twenty-four hours, others require many days, or even months. Hard seeds, such as those of some Palms, lie long dormant. Large seeds are slower in germinating than small ones, because they require more water, and their absorbing surface does not increase in proportion to their size. Seeds having an osseous or stony spermoderm, and those which are sown naturally while contained in a hard pericarp, as nuts and achenes, germinate more slowly than others. The germination may be expedited by thinning or chipping the envelope, so as to allow water to penetrate more easily. Many of the seeds inclosed in a hard shell or stone germinate in the midst of a decaying mass, which must contribute to the decomposition of the shell. Soaking hard seeds in water, or causing them to pass through the digestive canal of animals, greatly accelerates germination. The seeds of Hawthorn, and others of a similar nature, are thus often deposited by birds in peculiar localities in a state fit for immediate germination.

Alphonse De Candolle examined the germination of seeds in the open air and in a stove, and the following table shows the general results :-

NAMES OF SPECIES.	NUMBER OF DAYS REQUIRED FOR GERMINATION.		
	In the open air, 464° to 53.6° F.	In a stove. 64.4° to 77° F.	
Erigeron caucasicum Thlaspi ceratocarpum Dolichos abyssinicus Zinnia tenuiflora. — coccinea Grahamia aromatica	10 8 10 11 22 14	2 4 3 5 5 5 5 5 5 5 5 5 5 5 5 5 5 5 5 5 5	
Solidago hirta Lablab vulgaris Anthemis rigescens Rheum undulatum Duvaua dependens		10 6 7 16	

The rapidity with which some annuals germinate in arctic regions when the heat of summer returns is very remark-They pass through their periods of germination, flowering, and fruiting in a very short period. Such is also the case in warm countries after the dry season. After the dry season in the Brazilian plains, and when the first few showers have fallen, Gardner remarked that the annual Grasses pushed forth their blades with astonishing rapidity and vigour. Spruce states that on the sandy shores of the Amazon and Tapajoz, after the waters leave them, several small annual or rather ephemeral plants spring up. They start up from the sand, flower, and ripen their seeds in the that yielded more than one-half the seeds sown, viz., 15 out course of a few days, and then wither. Amongst them are

an Alisma, two or three Eriocaulons, a Xyris, and some minute Cyperaceæ.

Chemical changes during Germination.—During the germination of seeds, alterations take place in the nature of their contents. When the embryo occupies the entire seed, changes occur in the cotyledons, by means of which nutritive matter is prepared; when there is a separate store of perisperm, its constituents are acted upon by moisture, heat, and air, so as to undergo chemical changes. Alterations take place in the azotized matter, and part of the fibrin gives origin to diastase, which acts as a ferment; acetic acid is also formed, and the starchy matter is converted into dextrin and grape-sugar. Thus insoluble matters are rendered soluble, and a large amount of saccharine matter is produced. At the same time there is an evolution of carbonic acid, in consequence of a combination between the oxygen of the air and the carbon of the seed, and as the result of this chemical action a certain amount of heat is developed. The heat is carried off very rapidly by the soil in ordinary cases, so that it is difficult to ascertain its amount; but when seeds are laid in moist heaps the increase of temperature becomes

In the malting of Barley these changes are well seen. The grain is steeped in water in the first instance, so as to soften and swell; it is then laid in heaps 30 inches deep for 20 or 30 hours. In this situation it becomes warm, and germination commences. This is moderated by laying the grain in thin strata of a few inches thick, on large airy but shaded floors. There it remains 12 or 14 days, until germination is sufficiently advanced, being frequently turned in the meantime, in order to allow each grain to germinate equally, and to prevent entangling of the radicles of contiguous During this process sugar is formed, which is intended for the nourishment of the young plants, and if left long it would all be absorbed. This is prevented and germination stopped by exposing the grain in a kiln to a temperature rising from 100° to 160° or more. Thus the grain is

dried and its vitality destroyed.

During germination it is probable that there is a certain electric disturbance. Carpenter says, the conversion of the starch of the seed into sugar involves the liberation of carbonic acid, and of a small quantity of acetic acid. Now as all acids are negative, and as like electricities repel each other, it is probable that the seed is at that time in an electro-negative condition. Hence germination is said to be quickened by connecting the seed with the negative pole of a feeble galvanic apparatus, whilst it is retarded by being connected with the positive pole.

Acotyledonous germination.—When the spores of the lower Acotyledonous plants germinate, they send out cel-

lular processes of a more or less conical form, which serve the purpose of roots, and which often divide. These cellular prolongations may be formed from the entire walls of the spore, or from its inner covering. In Fig. 413. Germinating spores of a species of Liverwort (Marchantia) in which there is a protrusion of root-like processes. When these tubular prolongations are protrude through the context of the spore. from the entire walls

Fig. 413. Fig. 414.

tubular prolongations protrude through the outer coat of a spore, they exactly resemble the pollen tube, which may be considered as the result of the germination of a single cell placed on the stigmatic surface—the soil fitted for its growth (Fig 388). In Figure 414, the spore of a Seaweed (Fucus Botany. canaliculatus) is represented during germination, with its cellular roots protruded through the epispore. In these germinating spores one part appears as a root-like portion, while the opposite end is developed as a thallus bearing fructification.

In the case of Fungi, there is produced a peculiar subterranean axis called mycelium or spawn, on which the fructification is ultimately developed (Fig. 369 a). This mycelium spreads equally on all sides from the original point of development. In this respect it is analogous to the thallus of Lichens. In the case of many Agarics numerous pilei arise from the outer part of the mycelium in the form of a circle, and thus a fairy ring is formed; in the same way as in many Lichens the thallus spreads in a circle, and at its extremities produces fructification or apothecia. A large fairy ring, formed apparently from many individuals of one species of Fungus disposed in a circle, really constitutes the organs of fructification of a

single individual only.

The spores of many of the lower Acotyledons, such as Fungi, are so minute as to be easily scattered by the wind, and thus they are sometimes developed in very anomalous situations. Spores sometimes find a nidus in diseased structures in man and animals. Thus, in the disease of the skin called Porrigo favosa, as well as in Mentagra and Aphthæ, peculiar cellular bodies are produced, which appear to be altered and metamorphosed vegetable forms. In the case of the Silkworm, a Cryptogam called Botrytis Bassiana is found in a disease to which they are liable, and which has been called Muscardine. Caterpillars exhibit occasionally germinating spores of species of Sphæria. Sphæria Robertsii grows on the larva of Hepialus virescens in New Zealand. Other Sphærias are produced in similar situations. Species of Polistes are seen flying about in the West Indies with vegetable growths projecting from them. They are called vegetating wasps. Leida finds numerous fungal forms infesting the intestines of different species of Iulus, and also attacking the Entozoa in the intestinal tube of the animal. The spores of Fungi are diffused in the air, ready to alight on any body which can furnish a nidus for them. In this way various kinds of Mould are developed—the spawn or mycelium produced from the spore ramifying through the decaying matter, and sending up at intervals fructification. In some cases the mycelium becomes remarkably developed, and does not produce ordinary spore-bearing organs. Thus in vinegar and syrup a fungoid mass is often produced, which is probably a modified form of some kind of Mould. The Vinegar-plant seems to be a peculiar mycelial development of the Mould called Penicillium glaucum. During the germination of the spores, certain changes are induced in the fluid surrounding them. Thus a saccharine solution is converted into vinegar. The mycelium is sometimes formed in separate layers, which can be detached from each other, so as to form independent vegetating masses. The spores of a Fungus (Merulius lachrymans), when introduced into wood, germinate, and produce the disease called dry-rot.

In higher Cryptogams the spore produces first a cellular prothallus, whence roots and reproductive organs proceed. In Mosses the germinating spore forms, in the first instance, a cellular prolongation, which becomes a conferva-like germ, whence buds arise, bearing the leafy plant with its fructification. This is shown in Figure 415, where a germinating spore, a, of a Moss is seen protruding a cellular process, which elongates and divides, as seen at b, and finally, as shown in Figure 416, forms a jointed cellular prothallus, p, whence buds are produced, a, b, bearing the leaves and the organs of reproduction. In Ferns the spore gives origin to a thalloid expansion, the prothallus, whence roots proceed, and ultimately the sporangiferous frond. In

Figure 417 there is represented the spore, s, of a Fern Botany. forming a cellular prothallus, which gives out root-like processes, rr, and finally bears the organs of reproduction.

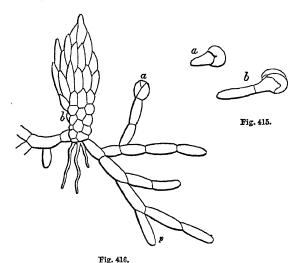

Fig. 415. Spore of a Moss (Funaria hygrometrica) germinating. The spore, a, gives out a cellular process, which elongates and divides, as seen at b. This produces the cellular prothallus.
... 416. The same Moss further developed, showing the cellular prothallus, p, or pro-embryo, with its roots, r, and buds, a, b, whence arise leafy stems bearing the organs of reproduction.

Monocotyledonous germination.—The embryo of a Monocotyledon has often at first sight no marked division of parts (Fig. 418). There is seen a slight projection at one end, r, which ultimately forms the root, and a uniform conical mass, which consists of the cotyledon, c, with the primary bud and axis; at the lower part there is a slit, s, which, as germination proceeds, gradually opens, so as to allow the plumule to protrude. The enveloping body is the single cotyledon.

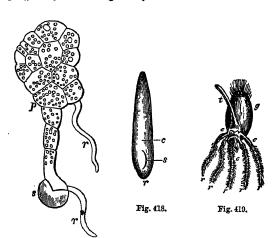

Fig. 417.

The prothallus bears the organs of reproduction, and gives origin to the sporangiferous frond.

418. Embryo of a species of Arrow-grass (Triplochin Barrelser), showing a uniform conical mass, with a slit, s, near the lower part. The cotyledon, c, envelopes the young bud, which protrades at the slit during germination. The radicle is developed from the lower part of the axis, r.

during germination. The radicle is developed from the lower part of the axis, r.

419. Grain of Wheat (Trificum) germinating. The embryo lies at one side of the grain, g. The radicular portion of the embryo gives off rootlets, r r r r, covered with cellular hairs. The principal root is the central one; the others being developed subsequently in succession. The roots pass through sheaths, c.c. The ascending axis, t, sheathed in the cotyledon, rises upwards.

In a monocotyledonous seed there is generally a supply Botany. of albumen, which is gradually dissolved and absorbed as germination proceeds. Sometimes the whole of the perisperm and its cells disappear; at other times, as in the seed of the Ivory Palm (Phytelephas macrocarpa), a portion is removed, and a sort of cellular skeleton is left within the seed. The radicular portion of the axis is more or less truncated, and sends off numerous rootlets, which pass through sheaths or coleorhizæ formed by the lower part of the axis. This is shown in the germinating grain of Wheat (Fig. 419), in which the rootlets, r, are covered with cellular hairs for the purpose of absorption. The central root is first developed, and the others come off in succession as secondary rootlets. When there is no albumen present, the cotyledon is usually pushed upwards beyond the seed.

In many perispermic monocotyledonous seeds the cotvledon is partly contained within the seed, and partly appears externally. That portion within the seed is called intraseminal, and corresponds to the blade or lamina of the leaf; the narrow protruded portion, which varies much in length, represents the petiolary portion, which often ends in a sort of sheath embracing the axis. In Figure 420, a representation is given of the seed of the Indian Shot in different stages of germination. A portion, c, of the single cotyledon remains within the seed, while another portion, a, protrudes, ending in a sheathing portion, s, which surrounds an axis, t, whence spring the radicles, rr, which pass through sheaths, col, and a primary bud, b, which rises to

The embryo is seen surrounded by the perisperm or albumen, p, which is inclosed within the integuments of the seed, or the general spermoderm, t. The micropyle is the point where the first part of the embryo protrudes, and the opening shows a lid-like process, t, which is raised in order to allow the passage of the germinating part. I. The seed in its early germinating state, with the radicular axis. r, protruding, sheathed by the cotyledon. 2. The embryo enlarged and the perisperm diminished, the radicular portion, r, more fully protruded, and the radicular continuation of the cotyledon, and the perisperm, p, diminished, a narrow portion of the cotyledon, a, protruded, ending in a sheathing portion, s, which embraces the axis, t, whence proceed the radicles, rr, passing through coleonize, col; and the first bud of the ascending axis, plumule, b, ascending.

form the stem. A similar development is observed in the Coco-nut.

In Grasses, as shown in Figure 63, the cotyledon, c, enlarges within the seed, and, on one side of the perisperm, roots, r, are protruded through sheaths, co, while the plumule, g, rises upwards, consisting of sheathing leaves arranged alternately. The sheathing cotyledon, c, with the radicle and the plumule, are also represented in the Maize or Indian Corn, in Figure 60. In all cases of monocotyledonous germination, after the radicles have descended into the soil, the plumule or first bud of the axis is developed, and the leafy stem is gradually formed. The leaves are usually alternate, and are often sheathing.

Dicotyledonous germination.—In dicotyledonous germination the radicle is protruded through the foramen of the seed, and then the cotyledons are either protruded, so as to appear above ground as epigeal leaves of a green colour, or they remain within the covering of the seed as fleshy hypogeal lobes, containing much nutriment in their substance. The first kind of germination is seen in Figure 421, where the embryo of a Sycamore is depicted with its radicular axis, r, giving origin to roots, its ascending axis,

Botany. a, with the two cotyledons, cc, which are green, leafy, and epigeal, inclosing the first bud, b. The second kind

> of dicotyledonous embryo may be illustrated by the Bean and Pea (Fig. 61), where the fleshy lobes, cc, which form the great bulk of the seed, are hypogeal, and are gradually absorbed during the

growth of the plant.

The dicotyledonous seed is sometimes exalbuminous or aperispermic, as in the Pea (Fig. 61), in which the fleshy cotyledons have a store of nutriment laid up in them for the growth of the embryo; at other times the seed is albuminous or perispermic, as in the Pansy (Fig. 335), and then the nutriment is separate from the embryo, and is gradually dissolved and absorbed during germination. Sometimes the two cotyledons become united, and when the embryo germinates they appear as one; at other times divisions take place, so that the embryo becomes polycotyledonous, as in Firs (Fig. 341). After the cotyledons have appeared they separate so as to allow the first bud, called plumule or gemmule, to be developed between them (Fig. 421, b). This bud forms the axis on which the leaves and flowers are produced. In proportion as the permanent leaves increase, the cotyledonary leaves (after acting as temporary organs of nutrition)

wither and fall off, and if they are subterranean they are gradually absorbed. The leaves which are produced in succession sometimes differ in their form. Thus in Victoria regia the youngest leaf is linear and almost filiform, the next is hastate, the third sagittate, and the fourth is nearly ovate, with a deep incision at the base. The future leaves gradually assume a more or less circular form, generally with a distinct line showing the place of the union of the lobes. The rate at which the axis increases varies according to the amount of temperature and moisture which is supplied.

CHAPTER IV.

SOME GENERAL PHYSIOLOGICAL PHENOMENA CONNECTED WITH VEGETATION.

I.—PROPAGATION OF PLANTS BY BUDS AND SLIPS.

Besides the propagation by means of seeds containing an embryo, or by cellular spores, plants are also capable of extension by division. In unicellular plants, and others of the lowest class, it is common to find each cell possessing the power of producing a new individual, either by simple division or by the formation of a cellular bud. In higher plants this mode of propagation is carried out by means of an assemblage of cells, which are developed into an organ or bud of a more complicated nature, before it is detached. Multiplication by division of cells is very common among the lowest Algæ, such as Desmidiaceæ and Diatomaceæ (Fig. 13). In the case of Lichens the thallus produces gonidia (Fig. 365, g), which appear to be a collection of cellular buds capable of producing independent individuals. On the

thallus of Liverworts (Marchantia) cup-like bodies (Fig. Botany. 362, g), are produced containing gemmæ. In Mosses the

power of reproduction by gemmæ is very marked.

The higher classes of plants may be considered as consisting of numerous buds united on a common axis. These possess a certain amount of independent vitality, and they may be separated from the parent stem in such a way as to give origin to new individuals. In some instances buds are produced which are detached spontaneously at a certain period of a plant's life. The bulbils or bulblets of Lilium bulbiferum (Fig. 75), and the cloves formed in the axils of the scales of bulbs are gemmæ or buds which can be detached so as to form new plants. Such is also the case with corms, as in Colchicum (Fig. 74). In these instances the buds are developed in the usual way in the axils of leaves or scales, that is to say, at the points where they join the stem. Some leaves naturally produce buds on their surface, as may be observed in Malaxis, Aspidium bulbiferum, and Nymphæa micrantha. Other leaves, when placed in particular circumstances, give rise to leaf-buds at their margin. Thus the leaves of Bryophyllum calycinum, when placed on the surface of damp soil, exhibit little shoots all around their edge (Fig. 141). The leaves of Dionæa muscipula can also be made to produce buds, and so can those of species of Gesnera, Gloxinia, and Achimenes. In some instances plants. in place of producing seeds, bear peculiar bud-like bodies on their floral axis. This occurs in what are called viviparous or proliferous plants, such as Festuca ovina var. vivipara, Aira alpina, A. cæspitosa var. vivipara, Poa alpina, Cynosurus cristatus, Polygonum viviparum, and in some species of Allium. In these viviparous plant (which are often alpine) alterations take place in different parts of the flower by which young plants are produced.

Besides this natural mode of propagation by gemmæ, new plants are also produced by divisions of the stem and branches. Many of the lower class of plants increase by a constant division of their axis or filaments. In the higher plants similar modes of propagation occur. Thus the potato is naturally reproduced by means of tubers which are shortened under-ground branches, and sections of tubers containing buds (eyes) produce separate plants. When some underground stems are cut to pieces every fragment is capable of giving origin to buds and new plants. This may be seen in many Carices growing in sand, in creeping grasses, and in the Horse-radish. Hence the difficulty of eradicating these plants. By means of slips or cuttings of the stem, gardeners propagate plants, more especially important varieties. These slips may be at once put into the soil, as in the case of Willows and Cactuses, and be made to put forth roots, or to strike, as it is called. By cuttings gardeners propagate Gooseberries, Currants, Figs, Vines, and some other plants. In deciduous trees the operation is best performed in winter. Sometimes gardeners employ layering, by bending down a branch into the earth, keeping it there with pegs, allowing it to form roots, and then cutting it off from the parent stem. In order to cause layers to form roots, they sometimes make a slit or notch on the shoot, or put a ligature round it, or ring the bark. In striking cuttings of plants, it is of great importance to attend to heat, light, and moisture, and to supply them in proper

Grafting.—Another mode of propagating plants is by grafting, or by taking a part of one plant and making it grow upon another plant. This process sometimes takes place naturally. The branches of trees, when they come into contact, especially when there is an abrasion of the bark, unite. The subject of grafting has received particular attention from Thouin and D'Albret, and it is fully discussed in the article Horticulture. By means of this process we propagate many woody, resinous, soft, or herbaceous plants, which either supply seeds rarely, or are difficult to strike

Botany. from cuttings or layers; and we perpetuate certain varieties, valued either for their fruit, the structure and form of flower, their colour, perfume, the nature of their wood, their general aspect, or the shades and variation of their foliage.

There are certain important requisites which must be attended to in grafting. In the case of Dicotyledonous trees, care must be taken to bring the growing parts into contact—the two alburnums and the two libers. The plants on which grafting is practised must be botanically allied, or at all events there must be a similarity in the composition of their sap. Union may take place between plants which, in their natural state, require the same chemical ingredients in the same proportions. This is generally the case with varieties of the same species, more rarely with plants of different species, and least frequently with such as belong to

Several advantages are derived from the multiplication of vegetables by grafts. We are enabled to perpetuate remarkable varieties which could not be produced by seed; we procure quickly many valuable trees, which are with difficulty multiplied by other means; we hasten the period of fruit-bearing; and we improve and propagate varieties of fruit trees. In the case of cultivated Apples and Pears, the seeds of our best fruits, such as the Ribston Pippin, the Nonpareil, and the Jargonelle, if sown, will not produce plants bearing these varieties of fruit, but they will have a tendency to reproduce the original species, viz., the Crabapple or Pear. By means of grafting we are enabled to continue esteemed varieties, and at the same time to impart vigour to young slips by putting them on good and wellgrown stocks.

The seeds of certain plants have a tendency to sport, as it is called, especially when highly cultivated and supplied with abundance of good nutriment. This is the case with the seed of the Crab-fruit when sown in good soil. By the art of the gardener an improvement is produced in fruit naturally sour and inedible. The seeds of such fruits, especially after a long period of cultivation, have a tendency to produce plants which bear fruit of a better quality than the Crab. Plants showing such a tendency are carefully preserved, and slips are taken from them and grafted on well grown stocks, and thus additional vigour is imparted. Grafting has the effect of supplying to the scion a store of nutriment ready prepared and at once fitted for use. Moreover, the nature of the stock imparts often certain qualities

to the fruit borne by the graft.

Mr Knight entertained the idea that the only true mode of continuing plants was by seed, and that a young shoot taken from an old tree could not be made to live longer than the natural term of life of the tree from which it was taken. On this principle he accounted for the disappearance, or at least the scarcity, of many well-known fruits, such as the Red Streak, the Golden Pippin, and the Golden Harvey. According to Mr Knight's theory, the vegetable individual is a plant which has originated from the development of a single seed; this individual may consist of many detached portions, each of which may exist apart from the others. A cutting of a tree is a part of the individual from which it was taken, and although it may have become a tree, still, according to Knight's view, it is no more than a developed state of a portion of the original plant. All parts of a tree are viewed as having a common end of their life, and different trees raised from one and the same tree by grafts are considered as decaying about the same time as the

These views have not been confirmed by the observations of physiologists. Experiments show that young shoots of old trees, when used as grafts or slips, furnish as vigorous plants as the shoots of young trees. A whole series of cultivated plants, such as the Vine, the Hop, the Italian Poplar, and the Weeping Willow, are constantly propagated by

division without any decreased power of vegetation being Botany. observed. There is no truth in the statement that propagation by seed is the only natural method of reproduction in plants. Many are propagated naturally by stems, bulbs, and tubers. The Sugar-cane propagates by the stem, which, when blown down by a storm, emits roots at every joint, the Tiger-lily propagates by bulbils, the Jerusalem Artichoke and the Potato by tubers, and the species of Achimenes by scaly bodies like tubers. Such modes of propagation do not cause debility, and there is no evidence of plants multiplied by division wearing out. There is however no doubt that cultivated plants become feeble by the influence of various causes, such as exhaustion of the soil, improper food, mutilation, the effects of cold, &c. It is also true that seeds or slips taken from diseased and weak plants will partake often to a certain degree of the constitution of the plants from which they have been taken.

While numerous experiments have proved that the young shoots of old trees, when used as grafts, furnish as vigorous plants as the shoots of young trees, and that Knight's views in regard to there being one common period of death for all parts of a tree, are erroneous, there is still wanting definite information as to the age which trees attain. The duration of their life has not been accurately determined. It exceeds so much the limit of man's life that it is not easy to collect data on the subject. Some exogenous trees attain a very great age. Trees which, in individual cases, attain great ages, belong to the most different natural families. Among them may be mentioned the Baobab, the Dragon-tree, species of Eucalyptus, Taxodium distichum, Pinus Lambertiana, Hymenæa Courbaril, species of Cæsalpinia and Bombax, the Mahogany tree, the Banyan, the Tulip-tree,

the Oriental Planc, Limes, Oaks, and Yews.

Some maintain that the stock and scion are incapable of producing any influence upon each other respectively, and that each retains to the last its own peculiar quality. This seems to be true, so far as their visible organization is concerned; for when grafted trees are cut down, the timber of the stock and scion remains just what it is in cases where no grafting has taken place, and the shoots that proceed from them generally manifest in like manner exactly their original There can be no doubt, however, that the nature of the stock has a decided effect on the slip or scion, both as regards its nutritive and its reproductive organs. it is stated, that Pears grafted on the Mountain Ash are rendered more hardy, and bear fruit earlier; and when grafted on Quinces they become higher coloured. Apples grafted on the Siberian Bitter-sweet Apple are more highly coloured than when grafted on the Crab. Peaches on Plum stocks are coarser than on Peach stocks. Beurré-Diel grafted on the Thorn produces hard fruit. This shows that the stock has an influence on the graft, and points out the importance of selecting stocks of good quality. The plan of ennobling fruit trees proceeds on the principle of grafting on superior stocks.

In some instances it appears that the slip or scion has a decided effect on the stock. Thus, according to Hales, if we bud the variegated Jasmine on a non-variegated one, it sometimes happens that the buds sent out from the latter bear variegated leaves. It is reported that at Chelsea the variegated White Jasmine was budded upon a branch of a fine plant of Revolute Jasmine with green leaves, and in the succeeding year a slight appearance of variegation came out on the leaves of the Revolute Jasmine. The next year the branch which had been budded was cut out, so that the Revolute Jasmine was thus apparently deprived of all influence from the variegated bud. Nevertheless, the variegation in the remainder of the plant continued to increase, and the leaves and branches ultimately became all variegated, even more than the White Jasmine, whose bud was origi-

nally inserted.

II.—DEVELOPMENT OF HEAT, LIGHT, AND ELECTRICITY BY PLANTS.

Temperature of Plants.-We have already seen that, during the periods of flowering and germination, a considerable amount of heat is evolved. This seems to depend on the combination between the oxygen of the air and the carbon of the plant, and is accompanied with the formation of grape sugar and the evolution of carbonic acid. The heat at these stages of growth is often very evident, more especially in cases where numerous germinating seeds are placed together, and numerous flowers are inclosed in a common covering. The phenomenon requires to be noticed in circumstances in which the heat cannot be carried off rapidly by the air or the soil. It is a matter of interest to determine whether or not heat is produced during the ordinary vital actions going on in the cells and vessels of plants. The investigation of this point has called forth the labours of several physiologists. Hunter instituted a series of experiments respecting the temperature of trees. He bored holes to the depth of ten or twelve inches in the trunks of trees, and inserted thermometers. He found that in spring, autumn, and winter the temperature of the internal part of a tree was usually about two degrees above that of the air. The results, however, were variable, and no satisfactory conclusions were deduced. Schoepf, Bierkander, Maurice, Pictet, and Schubler, made similar experiments, and they agree in giving to trees with thick trunks a temperature lower than that of the air during great heat, and higher than that of the air during extreme cold. In all these experiments the results seem to depend on the effects of the sun's rays, on evaporation, on the temperature of the soil as influencing the ascending sap, and on the bad conducting power of the wood.

While the nutritive processes are going on in the plant there is a certain amount of heat produced. This, however, is speedily carried away by evaporation and other causes, and it is not easily rendered evident. Dutrochet, by means of Becquerel's thermo-electric needle, showed an evolution of heat in plants. In doing this he required to prevent evaporation by putting the plant in a moist atmosphere. In these circumstances the temperature of the active vegetating parts, the roots, the leaves, and the young shoots, indicated a temperature above the air of $\frac{1}{2}$ to $\frac{3}{4}$ of a degree Fahrenheit. Van Beek and Bergsma, in their experiments on Hyacinthus orientalis and Entelea arborescens, found the proper heat of the active parts of plants about 1.8° F. above that of the air. The vital or proper heat of plants, according to Dutrochet, is found chiefly in the green parts, and it undergoes a quotidian paroxysm, reaching the maximum during the day, and the minimum during the night. When stems become hard and ligneous, they lose this vital heat Large green cotyledons gave indications of a proper heat. The hour of quotidian maximum varied from 10 A.M. to 3 P.M. in different plants.

Rameaux repeated the experiments relative to the temperature of the trunks of trees, and likewise those relating to the heat of the active vegetating parts of plants, and he came to the conclusion that the temperature of plants depends on two distinct sources-1. Organic actions going on in the young, soft, and herbaceous parts of plants, and which give rise to a temperature so slight that it requires delicate instruments to show it. 2. Meteorological influences, either immediate, as exercised on parts of plants exposed to the air, or mediate, as exercised on the soil and on the sap which is drawn up from it; the former being the most energetic. He remarks that in a tree at any one instant there are as many different temperatures as there are points unequally accessible to external sources of heat; that the sum of all these temperatures, or the entire heat of the tree, augments and diminishes with the surrounding

temperature; that the variations of temperature are more Botany. rapid and more intense in the superficial than in the deep layers, and that parts having a small diameter are cooled and heated with more rapidity and energy than those whose diameter is great; that during day the temperature of the different concentric layers of a tree diminishes in going from the surface to the centre, and that this diurnal distribution is established more or less quickly and completely according to the nature of the surrounding temperature and the diameter of the tree; that during the night, on the contrary, the temperature of the different layers increases from the surface to the centre, the nocturnal distribution varying in the same way according to the surrounding temperature and the diameter; that the action of solar rays is the most powerful cause of the temperature of plants; and that the ascending sap increases or diminishes the temperature of the parts it traverses according as these parts have a temperature lower or higher than its own.

Luminosity of Plants.—Considerable differences of opinion exist as to the luminosity exhibited by plants. Light is undoubtedly given out by Fungi in certain circumstances, but the occurrence of luminous phenomena in the higher plants is still a matter of dispute. Luminosity has been noticed in many species of Agaricus growing on dead or decaying wood, such as Agaricus olearius, indigenous in the south of Europe; Agaricus Gardneri, in Goyaz, Brazil; Agaricus igneus, in the island of Amboyna; and Agaricus noctilucens, in Manilla. The first two are of an orange colour, the third of an ash colour, and the fourth white. The light of the Agaric of the Olive-grounds (Agaricus olearius) may be compared to that of phosphorus; it is a continued white light without scintillations, very bright when the plant is young and recently gathered. Agaricus igneus has a bluish light. The whole plant of Agaricus Gardneri gives out at night a bright phosphorescent light, somewhat similar to that emitted by the larger fire-flies, having a pale greenish hue. From this circumstance, and from growing on a Palm, it is called by the inhabitants of Villa de Natividade, Flor de Coco.

Drummond describes two species of light-giving Agaricus found in the Swan River district. They grew parasitically on trunks of trees such as Banksias. placed on paper, the Agarics emitted by night a phosphorescent light sufficient to allow a person to read by it, and they continued to do so for several nights with gradually decreasing intensity as the plant dried up. Another phosphorescent Agaric was noticed by Mr Drummond in Australia on the trunk of a dead Eucalyptus occidentalis. The upper surface of the pileus was nearly black, while the central portion and the gills were milk-white, the stipe being

attached to one side of the pileus.

Some species of Rhizomorpha (which appear to be mycelia of Fungi) are remarkable for the phosphorescence which they display. These plants vegetate in dark caverns, and in the coal mines of Germany. They are seen hanging from the roof in great numbers. Their luminous qualities are most developed in the furthest recesses of the mines. Prestoc has noticed that the spawn of the Truffle (Fig. 366) is luminous, and that it may thus be collected at night in the Truffle-grounds. These are instances of luminosity in living Fungi, which disappears with life. Luminosity has also been observed in plants in a state of putrescence, as in rotten wood and in half-decayed potatoes.

Tulasne has made observations on the light given out by Rhizomorpha subterranea. By preserving it in a proper state of humidity the phosphorescence was kept up for several evenings. When the Fungus began to dry it lost its luminosity. Tulasne considers the light as similar to the phosphorescence in decaying plants, and he concludes that the same agents, namely oxygen, water, and heat, furnish the combination necessary for producing phospho

Botany. rescence, both in organized living beings and in those which have ceased to live. In both cases the luminous phenomenon accompanies a chemical reaction, which consists chiefly in the combination between organized matter and the oxygen of air, that is to say, a slow combustion, giving rise to carbonic acid.

The younger Linnæus states that the flowers of Nasturtium, the African Marigold, the orange Lily and other orange flowers, give out, at the end of a hot summer day. intermittent phosphorescence resembling little flashes of light. Dowden also mentions a luminous appearance of a similar nature in the common Marigold (Calendula vulgaris). He noticed it on the 4th of August 1842 at 8 P.M. after a week of very dry warm weather. A gold-coloured lambent light seemed to play from floret to floret, and to make a course round the disk of the flower. The light given out by flowers has been remarked by various other observers. These luminous phenomena in flowers are considered by Professor Allman as being merely optical illusions. He says they are only seen in orange and gaudy flowers, and at twilight, not in darkness, and that they must be traced to an intermittent effect on the retina.

The sap of plants is said to be luminous in certain instances. Mornay describes a tree in South America called Cipo de Cunanam, with a milky juice, which gave out in the dark a bright light when wounded. The phosphorescent light appeared at every cut in the stem, and each drop of the milky juice was luminous. Martius also observed the same kind of light in the sap of Euphorbia phosphorea, a Brazilian plant, when wounded. When this was observed, the temperature was 97.25° F., but it ceased when the heat sank to 68° F.; he did not find that it affected the galvano-

Electricity of Plants.-Some observations have been made relative to the electricity of plants, which may be referred to at this place. Pouillet stated that electricity was developed during the ordinary process of growth in vegetables. Several pots filled with earth, and containing different seeds, were placed on an insulated stand in a chamber, the air of which was kept dry by quicklime. The stand was placed in connection with a condensing electrometer. At first no electric disturbance was manifested; but the seeds had scarcely sprouted when signs of it were evident; and when the young plants were in a complete state of growth they separated the gold leaves of the electrometer half an inch from each other. The exhalation from leaves may be considered as a cause of the development of electricity, as well as the changes effected by leaves on the oxygen and carbonic acid of the atmosphere. Plants are considered as generally in a negatively electrical state. Dr Graves thinks that in this way, in tropical climates, where the superincumbent atmosphere is rendered positively electrical by evaporation from the sea, the negative state of plants leads to thunder storms. It is said that the pith and bark, as well as the two extremities of fruits, are in opposite states of electricity.

Wartmann has made an extensive series of observations on the influence of atmospheric electricity, and that of the battery, in the development of plants; on the influence of electricity on the circulation of the sap; and on the electric currents existing in the soil and in plants. He states that there are electric currents in almost all parts of plants; that in the roots, stems, and branches, there exists a central descending current and a peripherical ascending one; that there are also lateral currents between the pith and the cambium; that the electric state of the soil, and probably also the exhalation which takes place by the organs furnished with stomata, influences the electricity of the atmosphere around. Becquerel says, that in the act of vegetation the earth acquires continually an excess of positive electricity, the bark and part of the wood an excess of nega-

tive electricity; that the leaves act like the green part of Botany. the parenchyma of the bark—that is to say, the sap which circulates in their tissues is negative with relation to the wood, to the pith, and to the earth, and positive with regard to the cambium; that the electric effects observed in vegetables are due to chemico-vital actions; and that the opposite electric states of vegetables and the earth give reason to think that, from the enormous vegetation in certain parts of the globe, they must exert some influence on the electric phenomena of the atmosphere.

III.—VEGETABLE NOSOLOGY, OR THE DISEASES AND INJURIES OF PLANTS.

It would be difficult to name any department of vegetable physiology concerning which so little is positively known, even to those most conversant with such matters, as the nature of the diseases to which plants are liable. The number of writings on the subject is inconsiderable, and the information afforded by them still more so. The subject, nevertheless, is one of great importance. It is intimately connected with the prosperity of our forests and the productiveness of agriculture. Plants, like all other organized bodies, are subject to a great many accidents and diseases. The most common causes of disease are improper soils, ungenial climates, frosts, long-continued rains, great drought, violent storms, parasitic plants, insects, and wounds of various kinds.

According to Schleiden, plants in a state of high cultivation are all more or less in a condition predisposed to disease. There is an unnatural and excessive development of particular structures or particular substances, and thus, the equilibrium being destroyed, the plants are liable to suffer from injurious external influences. The general morbid condition produced by cultivation is heightened into specific predisposition to disease when the conditions of cultivation are opposed too strongly or too suddenly to those of The outward forms of diseases are sufficiently known, but the internal appearances are less understood, and for their proper apprehension they require a knowledge of vegetable anatomy, and especially of the physiology of cells. The characters are essentially similar in all living vegetable cells. There is a wall or membrane, composed of cellulose, lined by a viscid layer (the primordial utricle), composed of an albuminous matter abounding in nitrogen; the cavity of the cell is filled with watery juice, containing little nitrogenous matter, but having all the other compounds, such as gum, sugar, vegetable acids, inorganic salts, &c., dissolved in it. The chemico-vital force of the plant appears to reside in the nitrogenous layer; all growth depends upon it, and it does not disappear until the cell-wall has become properly developed. diseased plants are examined in the early stage, the first morbid appearance occurs in the nitrogenous layer, which becomes discoloured, coagulated, and granular, and the disease then extends to the cellular wall.

The diseases of plants may be divided in the following way:-1. Diseases which are caused by an excess or deficiency of those agents which are necessary for the vigorous growth of plants; such as soil, light, heat, air, and moisture.

2. Those which are either originally caused, or, at all events, aggravated and modified by the attacks of parasites, more particularly belonging to the natural order Fungi. 3. Those due to the action of poisons, either taken up from the soil or from the atmosphere. 4. Those caused by mechanical injuries of different kinds, as by the attacks of animals, more particularly insects. Diseases caused by changes in the atmosphere are often epidemic, and spread over extensive districts of country. Those which are due to parasitic Fungi are propagated by contagion—the minute spores being carried by the winds. Exciting causes operate with great intensity in cases where plants are previously predis-

Botany. posed to disease. Thus, if a plant is in an enfeebled or weak condition, it is very liable to suffer both from epidemic and contagious diseases.

The cryptogamic diseases of plants must be considered contagious, since they are produced by the contact of one portion of organic matter with another. The contact of diseased cells produces disease in healthy cells. Thus, if a healthy plant of Cactus be inoculated with some of the fluid from a plant affected with moist gangrene, diseased action will immediately commence and extend more or less rapidly. The action is analogous to what takes place with ferment when introduced into a saccharine liquid. The liability of the plant to the development of epidemic disease is produced by the state of the atmosphere as regards moisture, the prevalence of hot or cold weather, the amount of light, and probably the electrical condition of the air and earth, The natural decay of plants also renders them liable to attacks of Fungi.

Some of the causes we have noticed may operate together in producing disease. If, from defect of nourishment in the soil, a plant is stunted or weak, it becomes predisposed to disease, and is very liable to the attacks of parasites. A sudden frost coming on in spring, after the sap has begun to flow, causes severe injury, and either kills the plant or renders it liable to disease. This occurrence is common in Britain, and is the cause why many half-hardy exotics require to be covered or kept in a dormant state until the season has advanced beyond the risk of frost. Many such plants grown on a wall with a southern exposure are stimulated by the heat of a fine day in early spring, and are thus unable to resist later frosts. Warm sun during the day, and frost at night, have proved fatal to many exotics introduced into Britain. Plants are fitted by their constitution for different climates. Some will bear a great range of temperature without injury; others can only bear a limited one. Some require a hot summer and a cold winter; others require a medium summer and a moderate winter.

It has often been stated that tender exotics may by long cultivation be made to bear the climate of Britain. It has been thought that they may become accustomed to it by degrees, and thus be acclimatized. Some have even hinted that by sowing the seeds of such plants, in the first instance, in a warm temperate region, then collecting the seeds produced by the plants and sowing them in colder districts, the species may be rendered hardy. We are constantly told that plants which, when first introduced into Britain, were put into stoves and greenhouses, are now growing in the open border freely, and that they can stand a climate which they could not do at first. Such statements do not rest on a sound basis; each species of plant bears a certain range of temperature, and we cannot extend its natural limits. The plants said to be acclimatized were not tried in the open air when first introduced, otherwise they would have been found to be hardy, without any previous process of cultivation in greenhouses. The well-known shrub Aucuba japonica was treated in a stove when first introduced, and was afterwards planted out, and found to stand our climate. This was not an instance of acclimatizing, but indicated an error regarding the constitution of the plant, which was brought from the colder parts of Japan, and was capable of enduring the cold of this climate naturally. Man did nothing in the way of changing its constitution and powers of endurance. A plant called Aponogeton distachyum flowers freely in the open pond of the Edinburgh Botanic Garden. This plant was introduced from Southern Africa, and was at first grown in stoves. A specimen was accidentally thrown into the garden pond many years ago, and there it has continued to thrive ever since, flowering during almost the whole year. The roots of the plant are deep in the water, and the pond is supplied by springs. Had it been put into the pond when first introduced, the same result

would have followed. We are too apt to suppose that plants Botany. coming from countries called hot, must necessarily be stove plants; not reflecting that they may have grown in very elevated and cold regions in these countries. Such is the case with many species introduced from Chili, Nepal, and Japan. There is no evidence that plants long cultivated in this country are able to withstand our winter cold better than formerly. The Dahlia, the Heliotrope, and the Potato, are affected in the same way by frost as when they were first introduced. Long cultivation has done nothing to increase their hardiness.

Cold and bad soils are fruitful sources of disease. When plants are grown without the influence of light, they assume a white or yellowish aspect, thus becoming blanched or etiolated. In certain instances plants, even when exposed to light, present a pale and sickly hue, which is often referrible to the nature of the soil, or to constitutional weakness. In many crops we observe plants having a pallid aspect owing to ungenial weather and damp soil in the first in-The diseased state thus induced is called by Berkeley chlorosis; some have recommended for its removal the application of a weak solution of sulphate of iron along with draining. Plants, whose natural habitat is shady, become diseased when excess of light is supplied. Frosts, as well as excess of heat, render the stamens and pistils abortive. Spotting of the leaves, and canker of the stem, are often due to similar causes. When moisture is supplied in too great quantity, the plants become dropsical; and when the transpiration exceeds the absorption, the leaves often fall off. The dry and hot atmosphere of rooms often causes defoliation and disease in plants. Excessive development of hairs is sometimes a consequence of growing plants in very dry air. Diseases caused by changes in the atmosphere are often epidemic, and attack large districts of country.

The influence of the sea breeze, carrying with it saline matter, is prejudicial to most plants. Plantations are frequently injured from this cause. A good illustration is seen at Gosford, near Edinburgh, where the trees, on reaching the top of a wall, are stopped in their growth by the sea breeze, and their tops form an inclined plane proceeding inwards from the wall as a base. Some plants withstand this influence better than others.

The attacks of parasitic Fungi cause extensive injury and disease in plants. Some think that the spores of Fungi coming into contact with the plant act both as the predisposing and exciting cause of disease; others, perhaps more correctly, think that some change is first produced in the cells of the plant, which enables the spores to find a nidus, and then the disease goes on rapidly, assuming a peculiar type on account of the presence of the Fungus. In the same way as vegetable organisms found in diseases of the skin are not to be looked upon as the origin of the disease, but as being developed in textures previously morbid, and as giving often a peculiar character to the disease. Many of the diseases of cultivated crops are attributed to Fungi. The spores of Fungi are very minute, and are constantly floating in the air. They can easily be applied to the surfaces of plants. When they find an appropriate soil they send out extensive filiform ramifications which spread under the epidermis of plants, raise blisters, and finally burst forth in the form of orange, brown, and black spots constituting the fructification. They attack the stem, leaves, flowers, and fruit. Different species are restricted to different plants, and even to different parts of the same plant. The forms which the same Fungus assumes seem to vary sometimes according to the plant on which it grows.

The disease called Bunt, Smutballs, or Pepper-brand, is occasioned by the plant called Uredo Caries by De Candolle, and Uredo fœtida by Bauer. It attacks the grains of Wheat, and may be detected in them in their earliest state. It is represented in Figure 422. It consists of excremely

Botany. minute globules of a dark colour, at first attached to a thread-

like matter or mycelium. The powdery matter or spores have a disgusting odour; hence the specific name given to it. The disease is propagated by contact.

Another disease, called Smut or Dust-brand, is caused by a Fungus called Uredo segetum. It resembles the Bunt Fungus in colour and shape, but its spores are not half so large, and it does not possess a fetid odour. This Fungus destroys the ear of Corn by first causing the innermost parts of the flower to become abortive, while the pedicels on which these are

The Fungus (Uredo Caries or Uredo fatida) which causes the disease called Bunt, Smutballs, or Pep-per-brand.

seated swell and become very fleshy. The Fungus then consumes the whole of this fleshy mass, and at length appears between the chaff scales in the form of a black soot-like powder.

The disease denominated Rust, Red-rag, Red-robin, and

Red-gum, is caused by a Fungus called Uredo Rubigo (Fig. 423). It forms yellow and brown oval spots and blotches upon the stem, leaf, and chaff. The spores burst through the epidermis, and are dispersed as very minute grains. The disease is common in Corn and in Grasses. Mildew is a disease caused by a Fungus denominated Puccinia graminis (Fig. 424). The ripe spore-. Fungus denominated

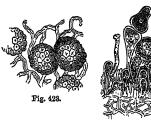

Fig. 424.

cases of this plant are small dark-brown club-shaped bodies, their thicker end being divided into two chambers, each filled with minute spores, and their lower end tapering into a fine stalk. The sori or clusters of spore-cases burst through the epidermis sometimes in vast numbers. The minute spores seem to enter the plant by the stomata. In the Vine a kind of mildew is traced by Berkeley to the attack of a Fungus called Oidium Tuckeri. For this disease sulphur, and the pentasulphide of calcium, have been recommended as remedies.

Henslow has shown by experiment, that if the diseased seeds of Wheat be steeped in a solution of sulphate of copper, they will not produce diseased grain, and that the sulphate of copper does no injury to their germination. The solution used is one ounce of sulphate of copper to a gallon of water for every bushel of Wheat. Grain also steeped in hot water did not reproduce these fungoid diseases. In East-Lothian, with the view of preventing Smut, seed Wheat is often steeped in stale urine, and afterwards some newly slaked lime sifted on it. Sometimes a solution of salt is used as a pickle.

Ergot is a monstrous state of the grain, in which the enlarged and diseased ovary protrudes in a curved form resembling a cock's spur; hence the name, from the French ergot, meaning a spur. The ovary is black externally, spongy internally, and contains much oily matter. Some consider it as produced by the attack of a Fungus, which induces a diseased condition in the ovarian cells. disease is usually met with in Rye,* and the name of CXXXVII. Spurred Rye is applied to it. It sometimes occurs in Wheat and in Barley, and it has also been noticed in other grains. Ergot consists of a very dense tissue formed by polygonal cells united intimately with one another, and filled

with an oily fluid. It is developed in the unimpregnated Botany. ovule of Rye; for although extremely dilated by the entophyte, and rendered difficult of recognition, the integuments of the ovule increase without completely losing the form which they would have assumed if they had grown into a true grain. The solid mass which has been called Sclerotium Clavus by De Candolle, and the filamentous portion called Sphacelia, by Leveillé and Fee, and Ergotætia by Quekett, are only, properly speaking, organs of vegetation. The Fungus destined to grow from this apparatus is an elegant Sphæria, probably that called by Fries Cordyliceps

purpurea.

The disease which has recently attacked the Potato in

various parts of the world, is by many attributed to the attack of Fungi. This view has been strongly advocated by Berkeley, who describes the Fungus as Botrytis infestans (Fig. 425). The spores are supposed to enter the stomata, and to cause disease in the leaves in the first instance, which afterwards extends to the tubers. The effects produced on the leaves by this disease resemble much those caused by poisonous gases, such as hydrochloric, poisonous gases, such as hydrochloric, sulphurous, and nitric acids. Berkeley attributes the Potato disease entirely to Fungi. He states that the disease commenced in the leaves. They were attacked by the Mould, which ran its course in a few hours, and from the rapidity of the action the period for examination of the leaves was often passed over. The Fungus acted by feeding on the juices

Fig. 425.

Fingus (Botrytis infestants), which occurs on diseased leaves of Potatoes, and Townley, to be the original cause of the late of the private of the leaves, and Townley, to be the original cause of the leaves, and Townley, to be the original cause of the leaves preading through the leaf, fructification bearing numerous spores. Fungus acted by feeding on the juices

Fig. 425. spores.

of plants, preventing the elaboration of the sap in the leaves, obstructing the admission of air and the emission of transpired fluids. While there is no doubt that the Botrytis is developed in the progress of the Potato disease, the question arises whether or not it is the originating cause. The view which seems to be most consonant with the phenomena is, that changes are induced in the cells of the Potato by cultivation, which render the leaves liable to disease. Atmospheric influences are thus enabled to act upon them, so as to cause alterations in their cells; and the attack of a Fungus such as the Botrytis accelerates the morbid action, and causes it to assume a peculiar form.

Crum attributed the disease of the tubers of the Potato to rupture of the starch cells and mixture of their contents with nitrogenous matter, thus causing fermentation, as in the Apple and Grape. Solly objects to the Fungus theory of Potato disease. He thinks that the disease is caused by the presence of putrifying azotized matter in the stem, just below the surface of the soil; that this is carried to all parts of the plant, causes a struggle between vital and chemical forces, and induces decomposition by a process of fermentation. The azotized matter, in a condition to act as ferment, is produced by the state of the season, by deficiency of light, and by other meteorological causes. Liebig attributed the Potato disease to diminished or suppressed transpiration depending on the hygrometric state of the atmosphere. He refers to Hales' accurate researches in regard to the Hop-blight, in which the disease is traced to the want of correspondence between absorption and transpiration, and a consequent stagnation and decomposition of the juices. The same thing, he thinks, takes place in the Potato in consequence of cold and an atmosphere loaded with moisture. Klotzsch proposes to check the Potato disease by repeatedly pinching off the extreme points of the branches and twigs. This check to the stem and branches leads, he thinks, to increased development of tubers, and strengthens the

Plate

*Plate

Botany. leaves and stalks. Tombelle Lomba of Namur says that he has saved Potatoes from disease by cutting off the stems, after flowering, with a very sharp sickle, and then covering the ground with earth to the depth of not less than one and a half inch. The top dressing thus applied was not disturbed until the Potatoes were ripe. The haulm was removed after being cut. It is said that the tubers acquired a good size, and were of excellent quality. If these facts are true, it would appear that, while leaves are necessary to the development of tubers, the latter, on acquiring a certain size, can continue their growth by their own proper and unassisted vitality. Bollman suggests drying the tubers at a high temperature as a remedy for the disease.

The general conclusions to be drawn from all that has been said relative to the Potato disease are, that changes are induced in the cells and vessels of the Potato by certain obscure meteorological and epidemic causes, that an alteration takes places in the cellulose and in the contents of the cells, which speedily leads to decay; that parasitic Fungi find a nidus in the decaying organic matter, so as to accelerate and give a character to the disease, and that as yet no

remedy has been devised.

Dry rot is a disease to which the wood of trees is liable. It may be traced in the first instance to some alteration in the woody tissue produced by moisture or other causes, and the subsequent development of a Fungus which spreads its mycelium through the texture, and produces rapid disorganization. Trees growing in wet and ill-drained soil are subject to rot. The more abundant the alburnum or sapwood, the more liable are trees to decay. The disease which has recently attacked the Larch is attributed by some to the roots reaching ungenial soil, and to the production of dry rot. In dry rot the decay takes place in the first instance in the contents of the woody tubes, and thus a suitable soil is supplied for the spores of Fungi, such as Merulius lachrymans or vastator, and Polyporus destructor. When these plants begin to grow, they spread their mycelium with great rapidity. If air is allowed to circulate freely around wood, dry rot does not attack it. But if it is placed in a damp situation without a circulation of air, then decay takes place. The spawn of the dry-rot Fungus deprives the woody tubes of their contents, for the purpose of getting the nourishment it requires, and the wood loses its consistency and toughness, the walls of the tubes becoming brittle and ruptured.

The great cause of decay in wood is moisture. Wood in a dry state may be preserved for a long time, as may be seen in the case of wood in some old buildings as Westminster Hall. To have timber in the driest state, it ought to be felled between the fall of the leaf and the spring, the nearer the former time the better. The timber of some trees is much more subject to decay than that of others. The wood of the Cypress is very durable. A great error in building is painting wood early, and thus inclosing within it the elements of decay by not allowing the escape of moisture. In olden times the wood was left bare, and exposed to currents of air which kept it dry, and hence its durability.

Various means have been proposed for preventing timber from being attacked by dry rot. Boucherie caused growing trees to absorb fluids of different kinds, which he considered as acting on the contents of the woody tubes in such a way as to render them less liable to disease. The solutions he employed were acetate of lead, pyrolignite of iron, and corrosive sublimate. He also found that trees, immediately after being cut down, when their extremities were immersed in these solutions, absorbed them with rapidity. Timber, after being cut, has been subjected to various processes for the purposes of rendering it durable. Kyanizing is performed by subjecting the wood to the action of corro-

sive sublimate, by means of which it is probable that the

albuminous matter is coagulated, fermentation is prevented, and hence the wood is rendered less liable to decay and to the attacks of Fungi. Kyan's solution is made to pass rapidly through wood in vacuo. Sir William Burnett found that the application of chloride of zinc to vegetable matters, such as wood and canvas, had the property of effectually guarding them against all the ordinary causes of destruction, without communicating any bad property to the substance prepared from it. Canvas so acted on was kept long in damp cellars, and exposed to various vicissitudes, without being injured, while ordinary canvas in similar circumstances became rotten. The process has received the name of Burnettizing. Burnett's antiseptic solution, of one pound of chloride of zinc to five gallons of water, has been tried in Woolwich Dockyard with success. Mr Bethell uses creasote for the preservation of wood. The creasote acts by coagulating the albumen, and preventing putrefactive decomposition.

Phanerogamous parasites are also injurious to plants.

Among them may be noticed especially species of Cuscuta* or Dodder (Fig. 426), which prove destructive to crops of Flax and Clover. Their seeds are sown with these crops, and germinate like other plants. Ere long they become attached to the stems of the plants in their vicinity by means of suckers, and then they act as true parasites, living on the sap of the plants, and finally destroying them. Other parasites, as Broom-rapes, and Mistleto, in a certain degree injure the plants on which they grow, but they are by no means so injurious as the Dodders. Loranths in Guatemala, by growing on the ends of branches of trees, cause the woody matter to be developed in a horizontal manner, so as to give rise to remarkable curved processes not unlike carvings.

Many substances act as poisons to plants as well as We have already animals. given full details in regard to the effects of poisonous gases CXXV.

Fig. 426.

A parasitic plant called Dodder (Cuscuta), which grows from seed in the usual way, with its roots in the soil, but afterwards twines round other plants, such as Treil and Flax, and attaches itself to them by means of suckers, a. It loses all connection with the soil, and lives on the plant, which it finally destroys. on vegetation. The experiments of Turner and Christison distinctly show that irritant gases, such as sulphurous, hydrochloric, and nitric acid, act by destroying first the parts to which they are applied, more especially those where there is abundance of moisture; while narcotic gases, like hydrosulphuric acid, have a general effect on the irritability of the plant. Marcet and Macaire experimented on the influence of fluid poisons on plants. They concluded that metallic poisons acted on vegetables in the same way as on animals. They were absorbed, and destroyed

the organs to which they were applied; while narcotic vegetable poisons destroyed the whole vitality of the plants, without any local irritation.

Injurious effects are produced on plants by insects of various kinds. Some of them feed on the plants; others form habitations for themselves in the leaves and flowers; others puncture different organs with the view of depositing their ova. Earcockle, Purple, or Peppercorn, is a disease caused by a minute animal called Vibrio Tritici, or the Eel of the Wheat. The disease was noticed by Needham more than a century ago. The infected grains turn dark green

Botany. at first, and ultimately nearly black. They become rounded, resembling a small Peppercorn, but with one or more deep furrows on their surface. The husk of the chaff spreads open, and the awns are twisted. The blighted grains are full of a moist, white, cottony substance, and contain no flour. When the cottony matter is placed in a drop of water under the microscope, a multitude of minute eelshaped animalcules are seen in active motion. They retain their vitality long. The mass may be allowed to dry, so that the slightest touch would reduce it to powder, and yet, when moistened with water, the animalcules will revive and become active. They may be dried and revived many times before they are killed.

Many trees, especially the Oak and Willow, are liable to the disease called Galls, which is due to attacks of insects (species of Cynips, &c.) The insects wound the bark and leaves while depositing their ova, and the irritation causes a formation of a deposit around them. The galls of commerce are produced on Quercus infectoria. In blue galls the insect is still in the interior, while in white galls the insect has escaped by a perforation. The Oak spangle is an appendage of the leaf attached by a central point to its under

surface; the inner side is smooth, the outer red, hairy, and Botany. fringed. Each contains a single insect, which retains its habitation till March, long after the leaves have fallen to the ground. These spangles resemble parasitic Fungi in their appearance, and have often been mistaken for them. The species of Spruce (Abies) are liable to a peculiar disease produced by the attacks of an insect called Adelges Abietis. This disease consists of an alteration in the colour and form of the leaves, which are aggregated together in the shape of cone-like excrescences.

The remedies proposed for the attacks of insects are numerous. Quick-lime, Sulphur, Turpentine, Tobacco, have all been recommended. In the case of Aphides the vapour of Tobacco is useful. It is not easy to get rid of the species of Coccus with their cottony covering. The only remedy seems to be the cleaning of the leaves and other parts of the plant by the hand. The vapour of sulphur will kill many insects, but then it acts injuriously on plants. A solution of Tobacco, the crushed leaves of the Cherry Laurel which give out a hydrocyanated vapour, ammoniacal liquor, coal tar, and many other substances, have been employed in different instances.

PART II.

TAXOLOGICAL BOTANY, OR THE CLASSIFICATION OF PLANTS.

CHAPTER I.

GENERAL REMARKS ON CLASSIFICATION.

In examining the Vegetable Kingdom, we observe that the individuals composing it are formed by the Almighty in accordance with a principle of order, as well as a principle of special adaptation. We have already remarked the order pursued in the arrangements of the various parts of the root, stems, leaves, and flowers of plants, and we have traced, in some degree, the modes in which they are fitted to perform their different functions. We now proceed to apply the facts of Vegetable Anatomy and Physiology to the classification of plants, and to consider the plan according to which they are grouped together in classes and families.

We see around us various kinds or sorts of plants which more or less resemble each other—or, in other words, are more or less related to each other. In Taxological or Systematic Botany we endeavour to mark these resemblances, and to determine their relations. It is impossible to give a scientific arrangement of the plants of the globe without a thorough knowledge of structure and morphology, and without an extensive acquaintance with the vegetation of all parts of the world. We cannot expect to determine the system on which plants have been grouped until we are familiar with all the forms which they present. Hence, in the present state of our knowledge, there must be imperfection in our attempts at systematizing. The Floras of many regions in Africa, India, China, Australia, and America, are still unknown, and we may therefore conclude that in all systems there will be gaps to be filled up as our knowledge increases. Sufficient, however, is known to enable us to group plants according to certain evident alliances.

The necessity for arrangement is evident, when we reflect that there are more than 120,000 known species of plants on the earth. In order to make these available for scientific purposes, it is absolutely essential that they should be named and classified. In associating plants in certain groups we naturally proceed on an idea of resemblance or likeness. While in ordinary language this idea is vague,

and is often founded on imperfect data, it is clear that in science it must be strict and rigorous. It is not enough to say that one plant resembles another in its general aspect, we must ascertain the particulars of agreement, and the points in which they differ; we must weigh well the importance of the characters, and must compare organs which are equivalent in value; and thus we shall often find, that plants which to common observers appear alike, are in reality totally different. The study of organography gives us a strict and accurate technical language which must be rigidly adhered to in classification.

Plants as they occur in nature are viewed as individuals resembling or differing from each other. Some individuals are so decidedly alike, that we at once give them the same names. Thus a field of Wheat is composed of numerous similar individuals which can be separated from each other, but cannot be distinguished by any permanent or marked difference. Although there may be some difference in size and other minor points, still we at once say they are stalks of Wheat. Every grain of Wheat when sown produces a stalk of Wheat; these stalks yield grains which produce individuals like their parents. The shoots or buds given off from the base of Wheat by tillering, also produce stalks of Wheat. On such universal and inevitable conceptions as these, our idea of Species is founded.

A Species may be defined as an assemblage of individuals presenting certain constant characters in common, and derived from one original protoplast or stock. The individuals are thus considered as having arisen from one parent stock. They may differ slightly in size, or in colour, and other unimportant respects, but they resemble each other more closely than they resemble any other plants, and their seeds produce similar individuals. Observation and common daily experience demonstrate, in the actual circumstances in which we exist, the permanence of the types which constitute the species of living bodies. There is no evidence whatever of a transmutation of species. The erroneous statements regarding the conversion of Oats into Rye have proceeded on imperfect observations. The individuals, however, of a species may present certain differences in regard to size,

Botany. colour, &c., these differences depending on soil, and on different conditions of heat, light, and moisture. Such differences are not incompatible with the idea of a common origin, and moreover, there is always a tendency to return to the original type. What are called *Varieties*, therefore, are variations in species which are not in general of a permanent character, and cannot be kept up in ordinary circumstances by seed. By cultivation, however, such varieties are sometimes perpetuated. This is usually accomplished by means of cuttings or grafts, and in certain instances even by seed. Thus the varieties of the cereal grains and of culinary vegetables have been propagated so as to constitute permanent races.

Plants which are cultivated are liable to sport, as it is called, and the peculiarities and variations thus produced are sometimes kept up. All the varieties of Cabbage, Cauliflower, Brocoli, Savoys, and Curled Greens are derived from one stock, Brassica oleracea. This plant grows wild on the sea-shore, and when cultivated it undergoes remarkable changes. Thus it forms a heart, as in ordinary Cabbage; its flower-stalks become thickened and shortened, as in Cauliflower and Brocoli; or its parenchyma is largely developed between the vessels, so as to give rise to the crisp and curled appearance of Greens. This tendency in the plant to produce monstrosities was early noticed by cultivators, and care was taken to propagate those individuals which showed abnormal appearances. The seeds of such were saved, put into good soil, and no plants were allowed to remain except such as presented the required form. In this manner certain races of culinary vegetables have been established. If, however, these cultivated plants are allowed to grow wild and scatter their seed in ordinary soil, they will in the progress of time revert to the original type or species. Instances such as these show the remarkable effects of cultivation in perpetuating varieties by seed.

In regard to the cereal grains, Wheat, Barley, Oats, &c., they have been so long cultivated that we are at a loss to know the original types or species. We have been forced, in the mean time, to call them species, although they are probably mere cultivated varieties of unknown species, perpetuated as races. That Wheat is an abnormal state of some plant, it has been remarked, might be conjectured from the fact that it does not become wild; if left to itself it disappears. Fabre has stated recently that the Wheat is a cultivated variety of the grass called Ægilops ovata. This plant first undergoes a change by which it becomes what has been called Ægilops triticoides, and then in successive years is converted into true Wheat. This discovery, as Lindley says, does not invalidate the characters by which the genera Ægilops and Triticum (as taken from wild species, such as Triticum maritimum, &c.) are separated, any more than the existence of a Peloria in Linaria invalidates the characters derived from the distinction between regular and irregular flowers.

It is of great importance to distinguish between mere varieties and true species, and to determine the limits of variation in different species. By not attending to this, many varieties have been described as species, and by their change or disappearance have given rise to great confusion and incorrectness both in descriptions and in arrangements. Another source of fallacy arises from hybrids being occasionally reckoned as true species.

Certain species not identical in origin, have common features of resemblance, and are associated together under what is called a Genus. A genus, then, is an assemblage of nearly related species, agreeing with one another, in general structure and appearance, more closely than they accord with other species. Thus the Scotch Rose, the Dog Rose, the China Rose, and the Sweet-briar, are all different species included in one genus, Rosa. It may happen that a single species may be reckoned as forming a genus, when

the peculiarities are as marked as those constituting other Botany. genera. Thus, if there was only one species of Oak, it would be sufficient to constitute a genus, as much so as at present when it includes 200 species. It is distinguished by its acorn from other allied genera, such as the Beech, the Hazel, and the Chestnut. The species in a genus present one general plan, and may be said to be formed after the same pattern. Some species of a genus, having special points of resemblance, may be grouped together in a Sub-

On looking at genera, it will be seen that some of them, such as Oaks, Hazels, Beeches, and Chestnuts, have a strong resemblance or family likeness, and that they differ remarkably from such genera as Firs and Pines, Maples and Ashes. Certain genera may in this way be grouped so as to form Orders or Families. While genera are groups of allied species, Orders are groups of allied genera, or, in reality, more comprehensive genera. Thus, Firs, Pines, and Larches, belong to different genera, but all agree in being cone-bearing, and are grouped under Coniferæ. The Rose, the Raspberry, the Bramble, the Strawberry, the Cinquefoil, the Cherry, and the Plum, all agree in their general organography, and are united under Rosaceæ. Certain genera have more points in common than others, and are grouped together under sub-divisions of orders called Sub-orders. Thus, the Plum and the Cherry have a drupe as their fruit, and are more nearly allied to each other than they are to the Apple; again, the Strawberry, Raspberry, and Bramble, are more allied to each other than to the Cherry or Apple. We have thus Sub-orders of Rosaceæ, namely, Amygdaleæ, including the Plum, Peach, Cherry, and Almond; Pomeæ, including the Apple, Pear, Medlar, and Quince; Potentilleæ, including the Strawberry, Cinquefoil, and Raspberry; and Roseæ, comprehending the Roses.

Certain orders agreeing in evident and important general characters are united together so as to form Classes; and subdivisions of classes are made in the same way as in the case of orders. There are thus Sub-classes associating certain orders included in one Class. The usual divisions are Classes, Orders, Genera, and Species. 'These occur in all systems of classification. A more minute subdivision may be made as follows:-

I. Classes. a. Sub-classes. II. Orders or Families. a. Sub-orders. b. Tribes. c. Sub-tribes.

III. Genera. a. Sub-genera or Sections. IV. Species. a. Varieties.

An enumeration of the marks by which one Class, Order, Genus, or Species is distinguished from another is called its Character. In giving the characters of any division, we notice merely those which are necessary to distinguish it from others. This is called its Essential Character. A plant may also be described completely, beginning at the root, and proceeding to the stem, branches, leaves, flowers, fruit, seed, and embryo. This is not essential, however, for the purposes of classification, and would be quite superfluous in that point of view. In the character of the Classes the important points of structure on which they are constituted are given. In the character of Orders (the ordinal character) we give the general structure of the included plants, especially of their flowers and fruit. In the Generic character we notice the modification of the ordinal character in a given genus-the character being taken from the parts of the flower and fruit, as in the order. In the Specific character are included certain less important modifications of form, whether in the stem, leaves, or flowers, which serve to distinguish allied species.

The essential character of a genus, when given in Latin, is put in the nominative case, that of a species in the ablative. The names of the Classes are variously derived, ac-

cording to the views of the authors in regard to the classification. They express some points of structure or development which are of marked importance or permanence. Orders are named from some characteristic genus included in them, except in artificial methods, where some organ is taken as the means of distinction. Genera are derived either from the Latin name of one of the species, from the structure or qualities of the included species, or from the name of some botanist, &c. Thus Prunus is a genus including the Plum, the Sloe, &c.; Rosa, the Rose; Papaver, the Poppy; Hookeria is a genus named after Hooker; Lithospermum, from two Greek words signifying a stone and seed, is given to a genus, the species of which have hard stony nuts or achenes.

In giving the name of a plant we mention its genus and species. Thus the common Dog-rose is called Rosa canina, the first being the generic name, the second the specific. Specific names may indicate the country in which a plant is found, the locality in which it grows, the form of its roots, stem, or leaves, the colour of its flowers, &c. A species named in honour of its discoverer or describer has the specific name usually in the genitive, as Veronica Jacquini, named after Jacquin. When the name is given in compliment to a botanist, without reference to the discovery, then the specific name is in the adjective form, as Veronica Lindleyana. Sometimes a generic name is used specifically, and then it is put as a noun after the genus, with a capital letter, and the two names may not agree in gender; thus we have such names as Cratægus Oxyacantha, Æthusa Cynapium, Viburnum Opulus, Veronica Chamædrys. To the genus and species are added certain letters, indicating the botanist who founded them. Thus Valeriana L. is the genus Valerian, as constituted by Linnæus, and Valeriana officinalis L. is the officinal Valerian, as described by Linnæus; Oxytropis, DC., is the genus so called by De Candolle. Sometimes authors happen to describe the same plant by different names. It is of importance, therefore, to give the Synonymes of other botanists, with their names. Thus Salvadora persica of Garcin is S. Wightii of Arnott, and S. indica of Wight's Illustrations. After the description of a plant we usually mention its Habitat, that is, the country or province in which it grows, with the nature of the locality, whether alpine or lowland, dry or moist, &c.

The following are some of the common abbreviations and symbols used by botanists:-

The names of Authors are abridged in Botanical works, by giving the first letter or syllable, &c. Thus, L. stands for Linnæus; DC. for De Candolle; Br. for Brown; Lam. and Lmk. for Lamarck; Hook. for Hooker; Hook. fil. for Hooker junior; Lindl. for Lindley; Arn. for Arnott; H. and B. for Humboldt and Bonpland; H. B. and K. for Humboldt, Bonpland, and Kunth; W. and A. for Wight and Arnott; Berk. for Berkeley; Bab. for Babington, &c.

The symbol ∞ or 00 means an indefinite number; in the case of stamens, it means above 20.

○ ① ① or A. means an annual plant.

of ⊙⊙ ⊕ ② or B. means a biennial plant,

24 △ or P. means a perennial plant.

b 5 or Sh. means a Shrub; T. a Tree.

) turning to the left; (turning to the right.

- 0 = Cotyledons accumbent, radicle lateral.

- v. s. s. Vidi siccam spontaneam, indicates that he has seen a dried native specimen.
- v. s. c. Vidi siccam cultam, indicates that he has seen a dried cultivated specimen.

CHAPTER II.

SYSTEMS OF CLASSIFICATION.

There are two systems pursued in the arrangement of plants; one is called the Artificial method, and the other the Natural method. In both of them the genera and species, or the minor divisions, are the same, but the higher divisions of classes and orders are totally unlike, and are founded on entirely different principles. The genera and species are very differently arranged in the two systems. In artificial methods one or two organs are selected in an arbitrary manner, and they are taken as the means of forming classes and orders; while in the natural method plants are grouped according to their alliance in all their important characters. Plants belonging to the same class and order in the former system may have nothing in common except the number of the stamens and pistils, or the form of their flowers, or some other arbitrarily selected character; while in the latter, plants in the same class and order are related by true affinity, and correspond in all the essential points of their structure and organography. When a student knows the artificial class and order to which a plant is to be referred, he does not thereby become acquainted with its structure and properties; plants diametrically opposed in these respects may be associated together. When he determines, on the other hand, the place of a plant in the natural system, he necessarily acquires a knowledge of its tsructural relations and affinities. Hence a knowledge of the latter system is that which must be the aim of every botanical student.

I.—ARTIFICIAL SYSTEMS OF CLASSIFICATION.

Attempts at an artificial methodical arrangement of plants were made by Cæsalpinus, Morison, Rivinus, and Tournefort, but the system which was most universally adopted was that of Linnæus, which was founded on the sexes of plants, and hence has been denominated the sexual system. It is called an artificial method because it takes into account only a few marked characters in plants, and does not propose to unite them by natural affinities. It is an index to a department of the book of nature, and as such is useful to the student. It does not aspire to any higher character, and although it cannot be looked upon as a scientific and natural arrangement, still it has a certain facility of application which commends it to the tyro. In using it, however, let it ever be remembered, that it will not of itself give the student any view of the true relations of plants as regards structure and properties, and that by leading to the discovery of the name of a plant, it is only a stepping-stone to the natural system.

In the artificial system of Linnæus, plants are divided into Flowering and Flowerless—the latter being included in the twenty-fourth class, under the name of Cryptogamia, and

Botany. the former, or Phanerogamia, being divided into twenty- in flowering plants they are determined by the number of Botany. three classes, the characters of which are founded on the number, the insertion or position, the relative length, and the connection of the stamens. Among flowerless plants

the styles, the character of the fruit, the number and connection of the stamens in those classes where these characters are not already taken into consideration, and on the herthe orders are similar to those of the natural system, while maphrodite or unisexual nature of the flowers.

The following are the Classes and Orders of the Linnæan artificial system:-

A. FLOWERING PLANTS, PHANEROGAMIA.

- I. Stamens and Pistils in every flower.
 - 1. Stamens unconnected.

a. Stamens either of equal length, or at all events need to in number. Class I. Monandria. 2 II. Diandria. 3 III. Triandria. 4 IV. Tetrandria. 5 V. Pentandria. 6 VI. Hexandria. 7 VII. Heptandria. 8 VIII. Octandria. 9 IX. Enneandria. 10 X. Decandria. 12 to 19,	ther didynamous nor tetradynamous:— Order 1. Monogynia 1 free Style. — 2. Digynia 2 free Styles. — 3. Trigynia 3 — — 4. Tetragynia 4 — — 5. Pentagynia 5 — — 6. Hexagynia 6 — — 7. Heptagynia 7 — — 8. Octogynia 8 — — 9. Enneagynia 9 — — 10. Decagynia 10 — — 11. Dodecagynia 12 to 19 — 12. Polygynia 20 or more.		
b. Stamens differing in length in certain proportions:—			
Two long and two short XIV. Didynamia	Order 1. Gymnospermia Fruit. Achenes		
Four long and two short XV. Tetradynamia	Order I. Siliculosa Fruit, a Silicula. 2. Siliquosa Fruit, a Siliqua. Fruit, a Siliqua.		
2. Stamens connected—			
By their Filaments in one a parcel or tube	Order Triandria 3 Stamens. — Pentandria 5		
By their Filaments in two parcels	— Pentandria 5 — — Decandria 10 —		
By their Filaments in three or more parcels XVIII. Polyadelphia	— Polyandria		
By their Anthers (Composite flowers)	 Order 1. Polygamia æqualis, florets all §. — 2. Polygamia superflua, florets of the disk ĕ, those of the ray ♀, but fertile. — 3. Polygamia frustranea, florets of the disk ĕ, those of the ray abortive. — 4. Polygamia necessaria, florets of the disk ħ, those of the ray ♀, and fertile. — 5. Polygamia segregata, each flower with a separate involucre. 		
With the Pistil on a column XX. Gynandria	Order Monandria		
II. Stamens and Pistils in separate flowers.			
On the same Plant XXI. Monœcia On separate Plants XXII. Diœcia	Order Monandria		
III. Stamens and Pistils in the same and in separate flowers on the same or on separate Plants	Order 1. Monœcia, &, &, and Q on the same plant. — 2. Diœeia, &, &, Q, on two plants. — 3. Triœcia, &, &, Q, on three plants.		
B. Flowerless Plants.			
Organs of reproduction XXIV. Cryptogamia	Order 1. Filices, Ferns. — 2. Musei, Mosses. — 3. Hepaticæ, Liverworts. — 4. Lichenes, Lichens. — 5. Algæ, Seaweeds. — 6. Fungi, Mushrooms.		
The system of Linnæus, even when regarded simply as	flower, it is impossible to determine its class and order.		

The system of Linnæus, even when regarded simply as an index to the vegetable kingdom, is by no means complete. The parts of flowers often vary in number, and cannot be confined within the strict rules required by this method of arrangement; moreover, unless the stamens and pistils are perfect and complete, and the plant is in full VOL. V.

When the system is rigidly adhered to, we find that species belonging to the same genus are separated. Thus the genus Lychnis has most of its species hermaphrodite, with ten stamens and five styles, but there is at least one British species diœcious. In order, therefore, to keep the genus

Botany. entire, and not separate the species, Linnæus adopted the plan of putting Lychnis in the class Decandria and order Pentagynia, and under the class Diœcia order Decandria, placing the name of the diœcious species, and referring the student to the 10th class for a description. In this way the genera-which are founded on natural affinities, and are not constructed by a mere arbitrary method—are preserved in their integrity. All the species of one genus are placed together, whether they accord or not with the characters of the class and order; the place of the genus being determined by the characters of the majority of the species. The names of the anomalous species are given in italics, in the classes and orders to which they belong according to the Linnæan method, and reference is made to the description of them as given under the genus.

II.—NATURAL SYSTEM OF CLASSIFICATION.

In arranging plants according to the Natural System, the object is to bring together those which are allied in all essential points of structure. It is called natural, because it proposes to follow the system of Nature, and thus takes into account the true affinities of plants on a comparison of all their organs. One of the first natural methods of classification was that proposed by Ray about 1682. He separated flowering from flowerless plants, and divided the former into Dicotyledons and Monocotyledons. His orders were founded on correct views of the affinities of plants, and he far outstripped his contemporaries in his enlightened views of arrangement. He may be said to have laid the foundation of that system which has been elucidated by the labours of Jussieu, De Candolle, Brown, Lindley, Endlicher, and others.

In arranging plants according to a natural method, we require to have a thorough knowledge of structural and morphological botany, and hence we find that the advances made in the latter departments have materially aided the efforts of systematic botanists. We may regard plants in various points of view, either with reference to their elementary tissues, their nutritive, or their reproductive organs. The first two are the most important, as being essential for the life of individuals, while the latter are concerned in the propagation of the species. These sets of organs bear a certain relation to each other, and we find that plants may be associated by a correspondence in all of them. In comparing the characters of plants, we must take care that we contrast organs belonging to the same class of functions, and the value of the characters must depend upon the importance of the functions performed by the organs.

Cellular tissue is reckoned of the highest value, as being of universal occurrence, and as carrying on, in many instances, all the functions of plants. In considering the elementary tissues alone, we divide all plants into Cellular and Vascular—the former including the lower tribes, such as Lichens, Seaweeds, and Mushrooms, the latter including the higher flowerless plants with scalariform vessels, and all the flowering plants with spiral vessels. In the nutritive and reproductive organs there is nothing which can be considered of the same value as cellular tissue. In the nutritive organs the embryo occupies the highest place, and by examining it we divide plants into Acotyledonous, having no cotyledons, but occasionally producing a prothallus, Monocotyledonous, with one cotyledon, and Dicotyledonous, with two cotyledons. Proceeding to the secondary organs in the nutritive class, we find that the root gives rise to the divisions of Heterorhizal, Endorhizal, and Exorhizal of Richard. Next the stem is Cellular or Thallogenous, Acrogenous, Endogenous, and Exogenous. The thallus is veinless, the frond of Acrogens has often a forked venation, the leaves of Endogens are parallel reined, and those of Exogens reticulated. In the reproductive system the sta-

mens and pistils occupy the highest place, as being the Botany. essential organs of flowering plants (Phanerogamia), while antheridia and archegonia have the same value in flowerless plants (Cryptogamia). Succeeding these organs in value comes the fruit, which is either a theca with spores, or a pericarp with seed. The floral envelopes are the next in the series; they are absent in Cryptogamous plants, and present in Phanerogamous; their arrangement is ternary ir Monocotyledons, quinary and quaternary in Dicotyledons The inflorescence and bracts, as found in flowering plants, occupy the lowest place in the subordination.

We thus find, that by comparing these different organs in plants, we arrive at certain great natural divisions, including plants which are associated by affinity of structure and function, as exhibited in the following table:-

Cellular Plants without Vessels or Stomata.	Vascular Plants with Scalariform Vessels, and Stomata.	Vascular Plants with Spiral Vessels, and Stomata
Acotyledonous { Heterorhizal. Thallogenous. No Venation.	Acotyledonous, with Prothal- lus. Heterorhizal. Acrogenous. Forked Venation.	Monocotyledon- ous. Endorhizal. Endogenous. Parallel Vena- tion. Dicotyledonous. Exorhizal. Exogenous. Reticulated Venation.
Cryptogamous. Thecæ with Spores, or naked Spores	Cryptogamous. Thecæ with { Spores.	Phanerogamous. Angiospermous or Gymnospermous.
Flowerless.	Flowerless. {	Floral Envelopes Ter- lopes Ter- nary. Flor. Env. Quater- nary or Quinary.
No Inflorescence nor Bracts.	No Inflores- cence nor Bracts.	Having Inflorescence and Bracts.

It is impossible to represent the affinities of plants in a linear series. Different groups touch each other at several different points, and must be considered as alliances connected with certain great centres. We find also that it is by no means easy to fix the limits of groups. There are constantly aberrant orders, genera and species, which form links between the groups, and occupy a sort of intermediate territory. In this, as in all departments of natural science, there are no sudden and abrupt changes, but a gradual transition from one series to another. Hence exact and rigid definitions cannot be carried out. In every natural system there must be a certain latitude given to the characters of the groups, and allowance must be made for constant anomalies, in as far as man's definitions are

Having examined the general principles upon which the natural system is founded, we shall now give a sketch of some of the more important Taxological plans which have been propounded. Jussieu divided plants into three primary groups-Acotyledones, Monocotyledones, and Dicotyledones, and included under them fifteen classes. One of the classes is Acotyledonous, three Monocotyledonous, and eleven Dicotyledonous. The three Monocotyledonous classes are distinguished by the position of the stamens, whether inserted on the thalamus (hypogynous), attached to the calyx (perigynous), or to the ovary (epigynous). Dicotyledonous plants are divided into Apetalous (monochlamydeous), plants having a calyx only; Monopetalous (gamopetalous), plants having united petals; Polypetalous, plants having separate petals; and Diclinous, plants which are unisexual and incomplete; the last constitutes the fifteenth class, while the other ten classes of Dicotyledons included in the other three divisions are determined chiefly by the position of the stamens and the corolla in relation to the ovary. Under these classes he included 100

Botany.

Tabular View of Jussieu's Natural System.

ACOTYLEDONES. Class I. Acotyledones. Stamens Hypogynous, II. Mono-hypogynæ. MONOCOTYLE-Stamens Perigynous, III. Mono-perigynæ. DONES. IV. Mono-epigynæ. Stamens Epigynous, Stamens Epigynous, V. Epistamineæ. Apetalæ, Stamens Perigynous, VI. Peristamineæ. (No petals). Stamens Hypogynous, VII. Hypostamineæ. Corolla Hypogynous, VIII. Hypocorollæ. Corolla Perigynous, IX. Pericorollæ. DICTOYLEDONES X. Epicorollæ, Syn-Monopetalæ, (Petals unitantheræ (Anthers united). Corolla Epigynous, ed). XI. Epicorollæ, Corisantheræ (Anthers separate). XII. Epipetalæ. Polypetalæ, Petals Epigynous, (Petals sepa-Petals Hypogynous, XIII. Hypopetalæ. Petals Perigynous, rate). XIV. Peripetalæ. Flowers unisexual, or without a Pe-XV. Diclines. rianth,

De Candolle's system is in many respects similar to that of Jussieu. He has the same primary divisions. Under Dicotyledons there are four groups, under Monocotyledons two groups, and under Acotyledons two groups. Among Dicotyledons the sub-classes are founded on the number of the floral envelopes, the union or separation of the petals, and the insertion of the stamens. Among Monocotyledons he included some Cryptogamous plants, and he formed two divisions, according as the floral envelopes were present or absent. The Acotyledons or Cellular plants were divided into those having leaves and those without leaves.

Tabular View of De Candolle's Natural System.

A. VASCULARES OF COTYLEDONEÆ.

Class I. Dicotyledones or Exogenæ.

Sub-class 1. Thalamifloræ. Petals distinct, stamens hypogynous. 2. Calycifloræ. Petals distinct or united, stamens perigynous or epigynous. Corollifloræ.

Petals united, hypogynous, usually bearing the sta-

4. Monochlamydeæ. Having a calyx only, or no floral envelope.

Class II. Monocotyledones or Endogenæ. 5. Mono-Phanerogamæ. Having floral envelopes.

6. Mono-Cryptogamæ. Without floral envelopes.

B. Acotyledoneæ of Cellulares.

7. Foliosæ. Having leaves. ••• 8. Aphyllæ. Leafless.

The following is the arrangement adopted by Lindley in his recent work on the Vegetable Kingdom:-

Class I. THALLOGENS—Asexual or Flowerless plants without proper stems or leaves, such as Fungi

II. Acrogens—Asexualor Flowerless plants, with stems

and leaves, such as Ferns.
III. RHIZOGENS—Sexual or Flowering plants, with Acotyledonous embryos and fructification springing from a thallus, such as Rafflesia.

... IV. Endogens — Monocotyledonous flowering plants with Endogenous stems, parallel venation, and ternary symmetry. This class is subdivided into

> 1. Plants with glumaceous flowers formed by imbricated bracts, such as Grasses.

Petaloid unisexual flowers, such as Palms.

3. Petaloid hermaphrodite flowers adherent to the ovary, such as Narcissus.

4. Petaloid hermaphrodite flowers free from the ovary, such as the Lily.

V. DICTYGGENS-Monocotyledonous plants with reticulated venation, including such orders as Dioscoreaceæ and Smilaceæ.

Class VI. Gymnogens—Polycotyledonous Exogens with naked Botany. seeds, as Coniferæ and Cycadaceæ.

... VII. Exogens—Dicotyledonous plants with seeds in a seed-vessel. Under this class he puts the following sub-classes :-

Sub-class 1. Diclinous Exogens, or Dicotyledons with unisexual flowers, and no tendency to form hermaphrodite flowers, such as Amenti-

Sub-class 2. Hypogynous Exogens, or Dicotyledons with hermaphrodite or polygamous flowers, and stamens entirely free from the calyx and corolla, such as Ranunculaceæ.

Sub-class 3. Perigynous Exogens, or Dicotyledons with hermaphrodite or polygamous flowers, the stamens growing to the side of either the calyx or the corolla, ovary superior, or nearly so, such as Rosaceæ.

Sub-class 4. Epigynous Exogens, or Dicoty-ledons with hermaphrodite or polygamous flowers, the stamens growing to the side of either the calyx or corolla, ovary inferior, or nearly so, such as Umbelliferæ.

The following is the arrangement which we propose to follow-De Candolle's system being taken as the basis, and some of the divisions being derived from Jussieu and Lindley:-

CLASS I. DICOTYLEDONES, EXOGENÆ, or ACRAM-PHIBRYA, in which spiral vessels are present; the stem is exogenous; stomata are present, the venation of the leaves is reticulated; the flowers have stamens and pistils, and the symmetry is quinary or quaternary; the ovules are either in an ovary or naked; and the embryo is dicotyledonous. In this class there are included four Sub-classes:

Sub-class I. THALAMIFLORE. - Flowers usually dichlamydeous, petals separate, inserted on the thala-

mus, and stamens hypogynous.

Sub-class II. Calversus.—Flowers usually dichlamydeous, petals either separate or united, stamens either perigynous or epigynous. This sub-class has two subdivisions-

1. Polypetalæ or Dialypetalæ—in which the

petals are separate.

2. Monopetalæ or Gamopetalæ—in which the petals are united.

Sub-class III. Corolliflor — Flowers dichlamydeous, petals united, corolla hypogynous. In this sub-class there are two subdivisions :-

1. Hypostamineæ—in which the stamens are inserted into the receptacle and not united to the corolla.

2. Epicorollæ or Epipetalæ—in which the stamens are inserted on the corolla.

Sub-class IV. Monochlamydeæ, or Apetalæflowers either with a calyx only or achlamydeous. In this sub-class there are two subdivisions

1. Angiospermæ-in which the ovules are contained in a pericarp, and are fertilized by the action of the pollen on the stigma.

a. Spermogenæ, having true seeds and a cotyledonous embryo.

b. Sporogenæ, having spore-like seeds and an acotyledonous embryo.

2. Gymnospermæ—in which the ovules are not contained in a true pericarp, and are ferti-lized by the direct action of the pollen without the intervention of a stigma, and the

embryo is polycotyledonous.

CLASS II. MONOCOTYLEDONES, ENDOGENÆ, or AM-PHIBRYA, in which spiral vessels are present; the stem is endogenous; stomata occur; the venation is usually parallel, sometimes slightly reticulated; the flowers have stamens and pistils, and the symmetry is ternary; the ovules are contained in an ovary; the embryo is monocotyledonous. Under this Class are included three Sub-classes:-

Botany.

Sub-class I. Dictyogenz-plants with reticulated venation in their leaves.

Sub-class II. Petaloider, or Floride-in which the leaves are parallel-veined; the flowers usually consist either of a coloured perianth or of whorled scales. This sub-class is divided into

1. Epigynæ—in which the Perianth is adherent. the ovary is inferior, and the flowers are usually hermaphrodite.

2. Hypogyna-in which the Perianth is free, the ovary is superior, and the flowers are usually hermaphrodite.

3. Incomplete-flowers incomplete, often unisexual, with no proper perianth, or with a few verticillate scales.

Sub-class III. GLUMIFER E-flowers glumaceous, consisting of imbricated bracts, venation parallel.

CLASS III. ACOTYLEDONES, or ACROGENÆ, and THAL-LOGENÆ, or THALLOPHYTA and ACRO-BRYA, in which the plants are either entirely cellular, or consist partly of scalariform vessels; the stem when woody is Acrogenous; stomata occur in the higher orders; the leaves are either veinless or have a forked venation; no flowers are present; the reproductive organs consist of Antheridia and Archegonia; spores or cellular embryos are produced which have no cotyledons. Under this class there are two divisions:-

Sub-class I. Acrogenæ, Acrobeya, or Cormogenæ —with a distinct stem, bearing leaves or branches. Sub-class II. Thallogene, Thallophyta, or Cel-LULARES-having no distinct stem nor leaves, but forming a cellular expansion of various kinds which bears the organs of reproduction.

CHAPTER III.

ARRANGEMENT AND CHARACTERS OF THE NATURAL ORDERS.

Having now considered the primary divisions of the natural system, we proceed to give the characters of the natural orders, which are associated under the different classes and sub-classes. We have already stated, that in a linear series it is impossible to group the orders according to their affinities. Each order is allied, not merely to those which immediately precede and follow it in such a series, but to various other orders which are necessarily removed from it. On the confines of classes and sub-classes, orders occur which have characters common to two or more of the groups, and we constantly meet with aberrant genera which form a connecting link between two orders. In Botany, as in all departments of natural science, there are no rigid lines of demarcation, but one division seems to pass into another by an insensible gradation. Our definitions express the most marked and important characters of the groups, without attempting to embrace all the anomalies; and as our knowledge of the vegetation of the globe advances, we are enabled to improve the definitions of the groups, and to form intermediate divisions.

I.—PHANEROGAMEÆ, COTYLEDONEÆ, OR FLOWERING PLANTS.

CLASS I.—DICOTYLEDONES, EXOGENÆ, OR ACRAM-PHIBRÝA.

SUB-CLASS I .- THALAMIFLOR E.

Natural Order 1 .- RANUNCULACEE, the Buttercup order (Figs. 427 to 429).—Herbs, rarely shrubs, with an acrid watery juice, and generally with much-divided, exstipulate leaves, the petioles of which are dilated, and sheathing (Figs. 117, 118, and 120). Sepals 3-6, usually deciduous, sometimes deformed. Petals 3-15, sometimes anomalous (Figs. 214, 215, 216), at other times suppressed. Stamens usually ∞ , with adnate anthers (Fig. 428). Carpels numerous, one-celled

pistil, Fruit, achenes (Fig. 317), follicles (Fig. 298), or baccate. Seeds anatropal, with horny albumen, and a minute embryo (Fig. 429). The plants of this order characterize a cold, damp climate, and when met with in the tropics, they occur on the sides and summits of mountains. They have narcotico-acrid pro-

perties, and are usually more or less poisonous. The acridity varies at different seasons, and in different parts of the plant;

Diagram of flower of Ranunculus, with five sepals, five petals, numerous stamens and carpels.

(Figs. 181 and 277), or united into a single, many-celled Botany.

Fig. 427.

it is frequently volatilized by heat, and destroyed by drying. Among the plants of this order may be noticed Aconitum Napellus, Monkshood, used to allay pain in neuralgia; Delphinium Staphisagria, Stavesacre; Helleborus officinalis (the black Hellebore of the ancients), H. niger, fætidus,* and *Pl. CX. other species, famed as drastic purgatives; and Podophyllum peltatum, May-apple, used in North America as a cathartic.

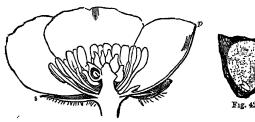

Fig. 428.

Fig. 428. Section of flower of Ranunculus, showing sepals, s, petals, p, numerous stamens, with adnate anthers, placed below the carpels.
429. Anatropal seed of Aconite, cut vertically, showing abundant homogeneous albumen, and a small embryo.

Nat. Ord. 2.—DILLENIACEÆ, the Dillenia order.—Trees, shrubs, or under-shrubs, with alternate, exstipulate leaves, five persistent sepals in two rows, five deciduous imbricated petals, indefinite stamens often turned to one side, a 2-5carpellary apocarpous or syncarpous fruit, arillate anatropal seeds, and homogeneous albumen. The species occur chiefly in Australasia, India, and Equinoctial America. They have astringent qualities, and some of them are large trees, which afford excellent timber.

Nat. Ord. 3.—Magnoliaceæ, the Magnolia order (Fig.

430).-Trees or shrubs, with alternate coriaceous sometimes dotted leaves, and convolute stipules, which cover the buds, and are deciduous. They are remarkable for the beauty of their foliage, and the fragrance of their flowers. Sepals, usually 3-6, deciduous. three or more, imbricated. Stamens o, distinct, with adnate anthers. Carpels, one-celled, nume-

Fruit, of numerous, dry or succulent, dehiscent or indehiscent, carpels. Seeds often arillate, and suspended from the fruit by a long funiculus; albumen fleshy and homogeneous; embryo minute. Magnolias abound in North America. The plants of this order have bitter, tonic, and aromatic quali-*Pl. OXI. ties. Drimys Winteri* yields Winter's bark; Illicium anisatum, on account of its flavour and the stellate arrangement of its fruit, receives the name of Star-Anise, Liriodendron tulipifera is the Tulip-tree (Fig. 430), remarkable for

its abrupt or truncated leaves. Nat. Ord. 4.—Anonaceæ, the Custard-apple order.— Trees or shrubs with alternate, entire, exstipulate leaves, three persistent sepals, six petals in two rows, usually valvate in

Botany, estivation, sometimes combined, numerous stamens covering a large hypogynous receptacle, numerous carpels containing one or more ovules, a succulent or dry fruit, consisting of a number of one or many-seeded carpels, distinct or combined, seeds with a brittle spermoderm, ruminate albumen, and a minute embryo. The species occur in tropical regions, and many of them furnish valuable fruits. The plants of this order are generally aromatic and fragrant. Anona squamosa yields the sweetsop, A. muricata the soursop, and A. reticulata the netted Custard-apple; A. Cherimolia produces the Peruvian Cherimoyer, said to be one of the finest fruits known.

Nat. Ord. 5.—Schizandraceæ, the Schizandra order.-Trailing shrubs, with alternate exstipulate leaves, allied to Anonaceæ, but differing in their habit, their unisexual flowers, their imbricate æstivation, and their homogeneous albumen. The stamens are often monadelphous, and the fruit consists of numerous baccate carpels. The species occur in India, Japan, and the hotter parts of North America.

Nat. Ord. 6.—MENISPERMACEÆ, the Moon-seed order.— Trailing shrubs with alternate, simple, usually entire leaves, and unisexual (often diœcious) flowers. Symmetry generally ternary. Stamens distinct or monadelphous, and attached to an androphore. Carpels supported on a gynophore, one-celled, containing a single curved ovule. Fruit drupaceous, one-celled, curved around a placental process. Seed solitary and curved; embryo with the cotyledons coiled up in a peripherical form. The woody matter is often closely compacted in wedges, separated by large medullary plates, giving the stem a peculiar aspect on a cross section. Menispermads are common in the tropical woods of Asia and America, and they climb among the trees to a great height. The plants of this order have narcotic and bitter properties; some of them are very poisonous. Anamirta paniculata yields the bitter narcotic fruit known in commerce as Cocculus indicus, and which has been sometimes illegally used to impart bitterness to malt liquor; Jateorrhiza palmata (Cocculus palmatus) supplies the bitter tonic root known as Calumba; Cissampelos Pareira, furnishes the tonic and diuretic root, known by the name of Pareira brava.

Nat. Ord. 7.—LARDIZABALACEÆ, the Lardizabala order. -Twining shrubs, with alternate exstipulate leaves, ternary symmetry and unisexual flowers, resembling Menispermads, but differing in their compound leaves, ovules sunk on the inner surface of the ovary, and minute embryo in abundant solid albumen. They are found in the cooler parts of South America and China.

Nat. Ord. 8.—Berberidaceæ, the Barberry order (Fig. 431).—Shrubs or herbaceous perennial plants, with alternate compound leaves, which are often spiny from nondevelopment of the parenchyma. Sepals, three, four, or six, deciduous, in a double row. Petals equal to the sepals in number, and opposite to them, or twice as many. Stamens equal in number to the petals, and opposite to them, anthers with two cells, each opening by a recurved valve from below upwards (Figs. 257 and 261). Carpel solitary, one-celled; stigma orbicular. Fruit baccate or capsular. Seeds anatropal; albumen fleshy and horny (Fig. 57). They are found in

Fig. 431, The flower of the Bar-berry, showing its se-pals, petals, and irrit-able stamens having ap-

temperate parts of the northern and southern hemispheres. In their properties they are acid, bitter, and astringent. The fruit of Berberis vulgaris, the common Barberry, contains oxalic acid, and is used as a preserve; while its bark and stem are astringent, and yield the bitter yellow crystalline matter Berberine.

Nat. Ord. 9.—Cabombaceæ, the Cabomba or Water- Botany. shield order.—Aquatic plants with floating peltate leaves. Sepals and petals three or four, alternating. Stamens 6-36. Carpels distinct, two to eighteen. Seeds definite; embryo in a vitellus, outside abundant fleshy albumen. They are allied to Nymphæaceæ and Nelumbiaceæ, and differ in their distinct carpels, definite ovules, abundant albumen, and nearly complete absence of a torus. They occur in America and New Holland.

Nat. Ord. 10.—NYMPHEACEE, the Water-Lily order (Figs. 432 to 434).—Aquatic herbs with large showy flowers,

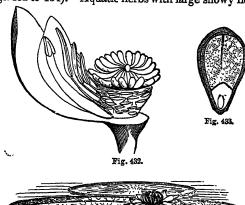

Fig. 434.

Fig. 432. Section of flower of Nymphesa alba, showing peduncle, torus or disk, petals, stamens with petaloid filaments, and radiating stigmas.

... 433. Seed of Nymphesa alba, cut vertically, to show the embryo in the vitellus or embryo-sac, with perispermic albumen.

... 434. Victoria Regia, the largest known Water-Lily.

and cordate or peltate leaves arising from a prostrate rhizome, which is sunk in the mud. Sepals usually 4, persistent. Petals numerous, deciduous, inserted on a fleshy torus, and passing by a gradual transition out of the sepals into the stamens, which are numerous, have petaloid filaments, and are inserted into the torus (Fig. 432). Ovary surrounded by the torus, many-celled, many-seeded, with radiating stigmas. Fruit indehiscent, pulpy when ripe. Seeds anatropous, attached to spongy dissepiments; embryo small, in a vitellus, outside farinaceous albumen (Fig. 433). There are considerable differences of opinion as to the position of this order. The structure of the rhizome resembles that of Endogens. The Water-lilies chiefly inhabit quiet waters in the northern hemisphere; they are rare in the southern hemisphere. The order possesses bitter, astringent, and some say narcotic properties. The plants contain much starch in their rhizomes, which are used for food in the same way as potatoes. Their petioles have large air-tubes, as well as spiral fibres, which can be separated and used for wicks. Victoria regia, Victoria Water-lily (Fig. 434), is found in the still waters of the whole of the warm parts of

Eastern South America. Its flowers, when expanded, are a foot and more in diameter. Its leaves vary from four to six or eight feet in diameter.

Nat. Ord. 11.—NELUMBIACEÆ, the Nelumbium or Water-Bean order (Fig. 435).—Aquatic herbs resembling Waterlilies, but differing in their large exalbuminous embryo, and their remarkation, larged tabular torus, in the hollow of which the nuts are half buried, and finally waters

Found in quiet waters

The enlarged honey combed torus of Neumbium with the nuts immersed in it. nous embryo, and their remarkably enof temperate and tropical regions in the southern hemi-

the order are remarkable for their large showy flowers and Their nuts are eatable.

Nat. Ord. 12.—Sarraceniaceæ, the Water-Pitcher or der.—Perennial herbs growing in bogs, with hollow pitcher-shaped or trumpet-shaped leaves (Fig. 139). Calyx usually consists of five persistent sepals. Petals five or 0. Stamens co. Style often expanding at its summit into a large peltate plate, with a stigma beneath each of its five angles. Fruit, a 2-5-celled capsule with axile placentas, bearing numerous albuminous seeds. The pitchers formed by the petioles of the leaves contain a peculiar secretion, the use of which is unknown. Sarracenia receives the name of Sidesaddle flower, in allusion to its tubular leaves. The plants are found abundantly in North America. Heliamphora occurs in Guiana.

Nat. Ord. 13.—PAPAVERACEE,* the Poppy order (Figs.

*PL CXII., and CXIII. figs. 6-11.

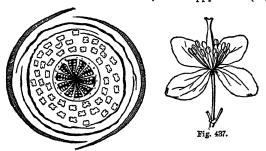

Fig. 436. Fig. 436. Diagram of the flower of the Poppy, showing two sepals, four crumpled petals, numerous stamens, pistil with parietal placentas.

437. Tetrapetalous corolla of Celandine and numerous stamens inserted below a pod-like pistil.

436 to 438).—Herbs with milky or coloured juice, and alternate exstipulate leaves (Fig. 121). Sepals two, rarely three, caducous (Fig. 208). Petals four (Fig. 437), rarely six, usually crumpled in æstivation. Stamens 8-24 or more. Fruit unilocular, siliquæform (pod-like), with 2-5 parietal placentas, or capsular (Fig. 309), with numerous placentas. Seeds numerous, with embryo in the midst of fleshy and oily albu-embryo and albu-men (Fig. 438). The order is chiefly confined

Fig. 438.

men (Fig. 438). The order is chiefly confined to Europe. Narcotic properties characterize the order. Some of the plants yield an acrid juice. Papaver somniferum is the Opium Poppy, the unripe capsules of which yield a milky juice, which, when concrete, constitutes opium. The active principle of opium is the alkaloid called Morphia, which is combined with meconic acid. Turkey opium is that chiefly used in Britain.

Nat. Ord. 14.—Fumariaceæ, the Fumitory order (Fig. 439 and Fig. 160).—Herbs with brittle stems, a watery juice, alternate, cut, exstipulate leaves, and irregular unsymmetrical flowers. Sepals two, deciduous. Petals four, cruciate, irregular, one or two of them often saccate or spurred, and the two inner frequently cohering at the apex, so as to include the anthers and stigma. Stamens either four and free, or six and diadelphous, each bundle being opposite the outer petals, and the central anther being two-celled, while the two outer are one-celled. Fruit, a round and indehiscent nut, or a one-celled and two-valved pod. Seeds crested, with a minute embryo and fleshy albumen. Fumeworts occur chiefly in temperate regions of the northern hemisphere. Some of them, as Dickstra spectabilis, are phous, each bundle being opposite the outer

Some of them, as Dickytra spectabilis, are very showy. They possess very slight bitterness and acridity. Nat. Ord. 15.—CRUCIFERÆ or BRASSICACEÆ, the Cruci-

sphere; very frequent in the East Indies. The plants of ferous or Cabbage order (Figs. 440 and 441).—Herbaceous Botany. plants with alternate, exstipulate leaves, racemose or corymbose flowers, usually yellow or white, and an ebracteated inflorescence. Sepals four, deciduous. Petals four, cruciate (Fig. 441). Stamens tetradynamous (Fig. 177). Fruit, a siliqua

Fig. 441. Fig. 440.

Fig. 440. Diagram of a Cruciferous flower, with four imbricate sepals, four petals, six stamens, tetradynamous, the two short ones solitary and opposite the lateral sepals, the four long in pairs opposite the anterior and posterior sepals, sulquose fruit, with two divisions to the right and left of the axis, separated by a replum, seeds attached by a funiculus to each side of the placentas. The floral symmetry is quaternary, but the stamens become six by collatoral chorisis of two of them, and the fruit bicarpellary by abortion of two of the carpels.

carpels. 441. Cruciferous flower of Brassica Eruca.

(Fig 314), or silicula (Figs. 315, 316). Seeds exalbuminous (Fig. 334); embryo with the radicle folded on the cotyledons (Figs. 337, 338). The plants are generally distributed, but abound in cold and temperate regions, especially in Europe. The order has been divided into sections, according to the nature of the fruit and of the embryo. The following are the divisions founded on the nature of the fruit:—1. Siliquosæ,—a siliqua, opening by valves (Fig. 307). 2. Siliculosæ, Latiseptæ,—a silicula, opening with two flat or convex valves, replum in the broadest diameter (Fig. 315). 3. Siliculosæ, Angustiseptæ,a silicula with folded or keeled dehiscent valves, replum in narrow diameter (Fig. 316). 4. Nucumentaceæ, -an indehiscent silicula, often one-celled, having no replum. 5. Septulatæ,-valves with transverse phragmata on their inside. 6. Lomentaceæ,—a pod dividing transversely into single-seeded portions, the beak sometimes containing one or two seeds, while the true pod is abortive. The divisions founded on the nature of the embryo are:—1. Pleurorhizeæ (Fig. 337),—cotyledons accumbent o — 2. Notorhizeæ (Fig. 338),—cotyledons incumbent o | . 3. Orthoploceæ, —cotyledons conduplicate o≫. 4. Spirolobeæ, —cotyledons twice folded o | | | . 5. Diplecolobeæ,—cotyledons thrice folded o | | | | . Crucifers are antiscorbutic and pungent, and occasionally acrid in their properties. None of them are poisonous. The order contains many of the culinary vegetables in constant use, such as Cabbage, Cauli-flower, Turnip, Radish, Sea-kale, Cress, and Mustard. The plants have much nitrogen and sulphur in their composition. Many garden flowers, as Wallflower, Stock, Rocket, and Honesty, belong to this order.

Nat. Ord. 16.— CAPPARIDACEÆ, the Caper order.— Herbs, shrubs, or trees with alternate leaves and tetramerous flowers; allied to Crucifers, but distinguished by the stamens being often indefinite, and if six, scarcely ever tetradynamous, by the want of a replum in the one-celled ovary, which is often supported on a gynophore, and by their reniform seeds. Capparids are chiefly tropical plants. In their properties, they resemble Crucifers. They have pungent, stimulant, antiscorbutic qualities. Capparis spinosa, in the southern parts of Europe, C. rupestris in Greece, C. Fontanesii in Barbary, and C. ægyptiaca in Egypt, supply Capers, which are the flower-buds of the plants.

Nat. Ord. 17.—RESEDACEÆ, the Reseda or Mignonette order.—Herbaceous plants, rarely shrubs, with alternate leaves having minute glands at their base, and racemose or spiked inflorescence. Sepals 4-7, sometimes united. Petals 2-7, lacerated and unequal, with broad or thickened claws (Fig. 213). Stamens definite, inserted on a fleshy disk. Fruit usually one-celled, opening early at the apex, with

Botany. 3-6 parietal placentas. Sometimes it appears as carpellary leaves surrounding a central placenta. Seeds several, reniform, or curved and exalbuminous; embryo arcuate. The plants of the order chiefly inhabit Europe and the adjoining parts of Asia and Africa.

Nat. Ord. 18.—FLACOURTIACEÆ or BIXACEÆ, the Arnotto order.-Shrubs or small trees, with alternate exstipulate leaves, often marked with round transparent dots. Sepals and petals 4-7, the latter sometimes 0. Stamens, same number as the petals or a multiple of them. Ovules attached to parietal placentas. Fruit one-celled, either fleshy and indehiscent, or a 4-5-valved capsule containing pulp, in which numerous albuminous seeds are enveloped. The plants are almost entirely natives of the hottest parts of the East and West Indies and of Africa. Some of the plants of the order are bitter and astringent, others yield edible fruits. Bixa Orellana has angular seeds covered with an orange-red pulp, which constitutes Arnotto, and is used for a red dye.

Nat. Ord. 19.—CISTACEÆ, the Rock-rose order (Figs.

442 and 443).—Shrubs or herbs, often viscid, with simple, entire leaves, and showy flowers. Sepals 3-5, persistent, unequal, the three inner with twisted æstivation. Petals five, very rarely three, caducous, often crumpled, twisted in an opposite direction from the sepals. Stamens definite or co, distinct. Fruit a one-celled capsule with parietal placentas, or imperfectly 3-5-celled by means of dissepiments arising from the middle of the valves, and bearing placentas the valves, and bearing placentas at or near the axis (dehiscence being loculicidal). Seeds

usually orthotropal, with mealy albumen; embryo curved or spiral. The plants are found chiefly in the south of Europe and

and other species

(C.ladaniferus, C. petals, indefinite stamens, ovary with numerous ovules, short style and peltate stigma.

Ledon), furnish the resinous substance called Ladanum, which is used as a stimulant and emmenagogue.

Nat. Ord. 20.-VIOLACEÆ, the Violet order (Figs. 444 and 445).—Herbs or shrubby plants, with usually alternate,

stipulate leaves (Fig. 136 and 169), having an involute vernation, and flowers ofter irregular. Sepals five, persistent, attached above their base. mens five, with short and broad

north of Africa.

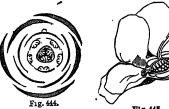

The Rock - roses

are generally resi-

nous and balsamic.

creticus,

Cistus

Petals five, often mequal, one bespals, five petals, five stamens with appending spurred. Stamens five with which section of the flower of a Violet characteristic five petals. centas.

445. Section of the flower of a Violet, showing the spurred petal, with a staminal appendage within it, and the ovary with numerous ovules.

filaments, which are often elongated beyond the introrse anther lobes; in the irregular flowers two of the stamens have appendages (Fig. 262); anthers sometimes united. Style declinate, with an oblique hooded stigma (Fig. 289). Fruit

a three-valved capsule, with parietal placentas in the middle Botany. of the valves (loculicidal). Seeds definite or ∞ , albuminous, anatropal, with a straight embryo. The species are found in Europe, America, Siberia, and Africa. The Violetworts are generally emetic, and some have purgative properties. In the roots of many of them a principle called Violin, similar to Emetin, has been found.

Nat. Ord. 21.—Droseraceæ, the Drosera or Sun-dew order.-Herbaceous marsh-plants, often covered with glandular hairs (Fig. 107); they have alternate leaves, with fringes at their base, and a circinate vernation. Sepals five, persistent. Petals five, imbricate. Stamens as many as the petals, or two or three times as many, distinct, withering. Styles 3-5, sometimes united. Fruit a onecelled, 3-5-valved capsule, with loculicidal dehiscence. Seeds numerous; embryo small, in the base of fleshy albumen. The plants are found in marshy grounds in various parts of the world, and have acid and slightly acrid properties.

Nat. Ord. 22.—Polygalaceæ, the Milkwort order (Fig. 446).—Herbs or shrubs with simple exsti-

pulate leaves. Pedicels have three bracts. and the flowers are irregular, unsymmetrical, and falsely papilionaceous. Sepals five, irregular, odd one posterior, two inner ones (wings) usually petaloid. Petals more or less united, usually three, of which one (the keel) is anterior, larger, and sometimes crested. Stamens 6-8, usually combined into a tube which is split on the upper side; anthers one-celled, opening by pores. Ovary usually two-celled, with a single pendulous, anatropal ovule in each cell; style curved. Capsule flattened with albuminous, carunculate seeds, containing a straight embryo. The order is considered by St Hilaire and others as considered by St Hilaire and others as

Fig. 446.

allied to Sapindaceæ, and some authors place it near Leguminosæ, from which it differs in its hypogynous stamens, and in the odd sepal being superior and the odd petal inferior. The plants are scattered over various quarters of the globe. They are generally bitter and acrid, and their roots yield a milky juice. Polygala Senega, Snake-root, is a North American species, the root of which is used as an emetic, cathartic, and sialagogue.

Nat. Ord. 23.—KRAMERIACEE, the Rhatany order.— The genus Krameria is the only one in this order which differs from Polygalaceæ in the want of the falsely papilionaceous flowers, in its simple one-celled ovary, and in the absence of albumen. Krameria triandra, which yields the Rhatany-root, is a native of South America. The root is very astringent.

Nat. Ord. 24.—Tremandraceæ, the Porewort order.— The plants of this order are slender, heath-like shrubs, with hairs usually glandular. They are allied to Polygalaceæ, and differ in their regular symmetrical flowers, valvate calyx, and hooked appendages at the apex of their seeds. They are found in New Holland.

Nat. Ord. 25.—TAMARICACEÆ, the Tamarisk order.— Shrubs or herbs usually growing by the sea-side, with entire, scale-like leaves, and spiked or racemose flowers. Calyx 4-5-parted, persistent. Petals 4-5, withering, imbricate. Stamens 4-5, or twice that number, free or united; anthers introrse, opening longitudinally Styles three. Fruit, a three-valved, one-celled capsule, with three basal or parietal placentas, bearing numerous anatropal, comose, exalbuminous seeds. Embryo straight. The species abound in the basin of the Mediterranean, and are confined to the northern hemisphere of the Old World. They have an astringent, and slightly bitter and tonic bark.

Nat. Ord. 26.—Frankeniaceæ, the Frankenia order.—

flowers embosomed in leaves. They are allied to Caryo-phyllaceæ, and differ in their parietal placentation, and straight embryo. They have a tubular furrowed calyx, and long-clawed petals with appendicular scales. They occur chiefly in the north of Africa and south of Europe. Their

properties are mucilaginous.

Nat. Ord. 27.—ELATINACEÆ, the Elatine or Waterpepper order.—Small annuals growing in marshes, with opposite leaves, interpetiolary membranaceous stipules, and minute axillary flowers. Sepals and petals 3-5. Stamens as many, or twice as many as the petals, distinct. Fruit a 3-5-celled septicidal capsule. Seeds numerous, attached to a central placenta, exalbuminous; embryo straight. order is perhaps allied to Rutaceæ, in which alliance it is placed by Lindley. The plants are found in all quarters of the globe. Their properties are said to be acrid; hence the English name of the order.

Nat. Ord. 28.—CARYOPHYLLACEÆ, the Clovewort order (Figs. 447 to 449).—Herbaceous plants with stems tumid

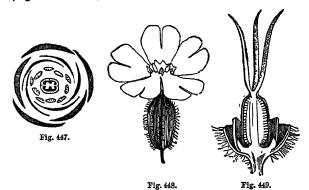

Fig. 447. Diagram of the flower of Dianthus, showing five imbricated sepals, which are united below, five imbricated and contorted petals, ten stamens in two rows, ovary at first with partitions, but finally one-celled with a free central placents.

448. Flower of Lychnis with gamosepalous calyx, five unguiculate and bifid petals having scales at the throat.

449. Flower of Lychnis out longitudinally, showing the capsule with its central placents and numerous ovules. Three out of five styles are left.

at the articulations, entire, opposite leaves, and cymose inflorescence (Fig. 168). Sepals 4-5, distinct or united (Fig. 203). Petals 4-5 (Fig. 448), unguiculate, sometimes 0. Stamens as many, or twice as many as the petals, sometimes fewer. Ovary often supported on a gynophore, usually one-celled, with a free central placenta (Fig. 449). Styles 2-5, papillose on their inner surface. Fruit a capsule opening by 2-5 valves, or by teeth at the apex (Fig. 308), which are twice as many as the stigmas. Seeds usually indefinite; embryo curved round mealy albumen (Fig. 336). The various species of Pink (Dianthus), and Chickweed (Stellaria), are included in this order. The plants are found principally in temperate and cold

Nat. Ord. 29.—VIVIANIACEÆ, the Viviania order.—Herbaceous or suffruticose plants, with opposite or whorled ex-stipulate leaves and regular flowers in corymbose cymes. They are characterized by a ten-ribbed valvate calyx, a marcescent corolla, ten free stamens, a three-celled loculicidal capsule, and albuminous seeds, with a curved embryo.

They are found in South America.

PI.CXIV. Nat. Ord. 30.—MALVACEÆ, the Mallow order (Figs. 450 and 451).—Herbs, shrubs, or trees, with alternate, stipulate, palmately-divided leaves, often stellate hairs, and showy involucrate flowers on axillary peduncles (Fig. 172). Sepals five, rarely three or four, united at the base, valvate, often having an epicalyx. Petals of the same number as the sepals, twisted. Stamens oc, monadelphous (Fig. 451), united to the claws of the petals; anthers one-celled, reniform, in-

Botany. Herbs or undershrubs, with opposite exstipulate leaves, and trorse, opening transversely (Fig. 249); pollen hispid (Fig. Botany. 266). Ovary many-celled, with placentas in the axis; or several ovaries, separate or separable when ripe; styles equal in number to the carpels, distinct or united. Fruit composed

of several monospermal or polyspermal carpels, either combined or separate. Seeds with little albumen; embryo curved with folded cotyledons. The plants abound in tropical regions, and in the hotter parts of the temperate zone. The properties of the Mallowworts are mucilaginous and demulcent. They supply various kinds of fibres. Althæa officinalis, Marsh Mallow, is used medicinally to supply mucilage. Various species of Gossypium
furnish cotton, which consists of the
hairs attached to the seeds. These
hairs are usually hollow cells, but
occasionally they become flattened.

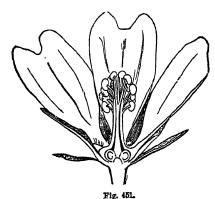

Fig. 450.

Diagram of flower of Mallow, showing three parts of epically or involuce, five parts of the valvate callyx, five ontorted petals, numerous control petals, numerous control

Fig. 450.

There are probably four distinct species of plants furnishing the Cotton of commerce:-1. Gossypium herbaceum, the

Vertical section of the flower of Mallow, showing epicalyx, calyx, corolla, monadelphous stamens, and the carpels.

common Cotton plant of India, a variety of which supplies the Chinese or Nankin Cotton. 2. G. arboreum, the Tree-Cotton of India. 3. G. barbadense, Barbadoes Cotton, called in India Bourbon Cotton; this supplies the highly-esteemed Sea Island Cotton. 4. G. peruvianum of Cavanilles, or G. acuminatum, which supplies the Pernambuco or Brazil Cotton. The inner bark of Hibiscus canabinus furnishes a kind of Sun-hemp in India.

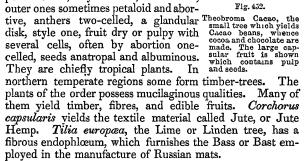

Nat. Ord. 31.—Sterculiaceæ, the Silk-cotton order.— Large trees or shrubs, with simple or compound leaves, and occasionally unisexual flowers, resembling the Malvaceæ in their general characters, particularly in their columnar stamens, but differing in their two-celled extrorse anthers. They are tropical plants. The Sterculiads resemble the Malvaceæ in their properties. Adansonia digitata, the Baobab tree, Monkey-bread or Ethiopian Sour-gourd, is one of the largest trees in the world, its trunk attaining a diameter of 30 feet. Bombax Ceiba, the Silk Cotton-tree, has a cottony matter surrounding its seeds, which is used for stuffing cushions and other domestic purposes. Durio zibethinus, the Durian, yields an edible fruit with a civetlike odour.

Nat. Ord. 32.—BYTTNERIACEÆ, the Chocolate order (Fig. 452).—Trees, shrubs, and undershrubs, with simple leaves, resembling the Sterculiaceæ and Malvaceæ, but differing from the former in their introrse anthers, slightly mona delphous, and often partially sterile stamens; and from the latter in their usually definite not columnar stamens, two celled anthers, and smooth pollen. The fruit is a capsule comFig. 452.

Botany, posed of a few carpels. They are chiefly tropical or subtro-

pical plants. In their properties Byttneriads resemble Malvaceæ. Theobroma Cacao, the Cacao-tree (Fig. 452), is a small tree which abounds in the forests of Demerara. From the seeds called Cacao-beans, the substances called Cocoa and Chocolate are prepared.

Nat. Ord. 33. TILIACEÆ, the Linden order.—Trees or shrubs with alternate leaves having deciduous stipules (Fig. 105), floral envelopes tetramerous or pentamerous, calyx valvate, stamens o, outer ones sometimes petaloid and abor-

Nat. Ord. 34.—DIPTEROCARPACEÆ or DIPTERACEÆ, the Sumatra-Camphor order.—Large trees with resinous juice, alternate, involute leaves, convolute stipules; long winglike, imbricate, unequal, calvx lobes; contorted petals; indefinite, distinct, or polyadelphous stamens, subulate anthers; coriaceous, one-celled fruit, surrounded by the calyx, the enlarged divisions of which form winged appendages; single, exalbuminous seed. Tropical Indian trees. The plants of this order yield a resinous balsamic juice which assumes various forms. Dryabalanops Camphora or aromatica, supplies the hard Camphor of Sumatra, and a resinous oily fluid called the liquid Camphor, or Camphor-oil of Borneo. The wood of Shorea robusta is much used in India under the name of Sál. Vateria indica furnishes the Piney Resin of India.

Nat. Ord. 35.—Chlænaceæ, the Leptolæna order.—Trees or shrubs with alternate, feather-veined, entire leaves, convolute stipules, involucrate flowers, which have three imbricate sepals, five convolute petals, numerous stamens, often monadelphous, a three-celled ovary, a capsular fruit, and albuminous seeds. They are found in Madagascar.

Nat. Ord. 36.—Ternströmiaceæ, the Tea order (Figs. 453 and 454).—Trees or shrubs with alternate coriaceous,

Fig. 454. Fig. 453. Thea Bohea, or Cantonensis, the plant which yields Black and Green
Tea at Canton.
454. Thea viridis, the plant of the best Tea districts of China, which supplies the Black and Green Tea generally used in Britain.

usually exstipulate, and entire leaves, showy and generally unsymmetrical flowers. Sepals 5-7, with imbricate æstivation. Petals 5, 6, or 9, often combined at the base. Stamens, ∞ , distinct or united. Fruit a 2-7-celled capsule, usually with a central column. Seeds large, very few, with

or without albumen. They are ornamental plants, found Botany. chiefly in Tropical America and in Eastern Asia. Those cultivated in Britain are principally from North America and China. The plants of the order have stimulating and slightly narcotic properties. Numerous varieties of Camel-lia japonica are cultivated, which are highly esteemed by florists. Thea is the genus which includes the various species and varieties of Tea. According to Fortune, there are two species of Tea, Thea Bohea (Fig. 453), and Thea viridis (Fig. 454), from each of which Black and Green Tea is manufactured. The latter species is that which supplies the Tea sent from China to Britain. The difference in the appearance and quality of Teas depends partly on the climate and species, but chiefly on the time of gathering, and the mode of manufacture. The young leaves, quickly dried and subjected to a particular kind of manipulation, supply the Green Tea, while the older leaves dried more slowly, and after undergoing a process of fermentation, constitute the Black Tea. In some instances Tea is dyed of a green colour by means of a mixture of Turmeric, Prussian Blue, and Gypsum.

Nat. Ord. 37.—OLACACEÆ, the Olax order.—Trees or shrubs, often spiny, with alternate, exstipulate leaves, a cup-shaped calyx, being enlarged with the fruit and often covering it, five valvate petals, 5-10 stamens, partly sterile, five fertile ones being opposite the petals, a disk, a succulent fruit with a hard endocarp, and an albuminous seed without integuments (exutive). An order of mostly tropical shrubs, containing few species. Some yield edible fruits.

Nat. Ord. 38.—ICACINACEÆ, the Icacina order.—Evergreen trees and shrubs allied to Olacaceæ, but differing in the calyx not enlarging with the fruit, stamens being alternate with the petals, ovary plurilocular, with axile placentation, and seeds having the usual integuments (indutive). The order is chiefly tropical.

Nat. Ord. 39.—CYRILLACEÆ, the Cyrilla order. Evergreen shrubs with exstipulate leaves, allied to Olacaceæ and differing chiefly in their imbricate not valvate petals, which are not hairy. They are found in North America.

Nat. Ord. 40.—AURANTIACEÆ, the Orange order (Figs. 455 and 456). Trees or shrubs with alternate, compound,

exstipulate, dotted leaves (Fig. 133), and fragrant flowers. Calyx short, urceolate or campanulate, 3-5-toothed. Petals, 3-5. Stamens equal in number to the petals, or a multiple of them, inserted along with the petals on a hypogynous disk cylindrical; stigma

Fig. 456.

(Fig. 456); filaments sometimes united in one or more bundles.

Ovary free; style cvlindrical: stigma

thickish. Fruit a hesperidium, sometimes, as in fingered Citrons and horned Oranges becoming monstrous by the separation of the carpels, or by the multiplication of carpels, so that one fruit is included within another. Seeds exalbuminous, often polyembryonous. Chiefly East Indian plants. The leaves and the rind of the fruit contain a volatile fragrant oil, and the pulp of the fruit is more or less acid. Ægle Marmelos, the Indian Bael or Bela, yields a delicious fruit; its root and bark are antispasmodic; the decoction and jelly of the fruit are used in diarrhœa. Citrus Aurantium, the Sweet Orange, has been so generally distributed over different quarters of the globe, that its native country can scarcely be

of the fruit yields an oil called Oil of Orange, while the flowers supply another kind of oil. The pulp of the fruit contains malic acid. C. vulgaris (C. Bigaradia of some authors), the Bitter or Seville Orange, is probably a variety. It differs from the Sweet Orange in the larger wing of its petiole, its more fragrant flowers, its darker fruit, and its more bitter rind and pulp. In the young state, the fruit is known as Orangettes or Curaçoa Oranges. The flowers yield an essential oil called Neroli oil. The distilled water of the flowers has hypnotic qualities. C. Limonum, the Lemon, yields an acid antiscorbutic juice. It contains citric acid. C. Limetta produces the Lime, and var. Bergamia, the Bergamot; C. medica is the source of the Citron; C. Decumana furnishes the Shaddock; C. paradisi the forbidden fruit; C. Pompelmos the Pompelmoose; and C. japonica, the Kumquat of China.

Nat. Ord. 41.—HYPERICACEÆ, the St John's Wort order (Fig. 457).—Herbs, shrubs, or trees, with a resinous juice,

regular flowers, opposite, entire, exstipulate leaves, usually with transparent dots and blackish glands. Sepals 4-5, persistent, two outer often smaller. Petals 4-5, unequal-sided, twisted in æstivation, often bordered with black dots. Stamens generally ∞ and polyadelphous. Carpels 3-5 partially united. Fruit a capsule with septicidal dehiscence. Seeds numerous and exalbuminous. The order is generally distributed both in warm and temperate regions. There are 280 known species. The properties of the plants are usually purgative; some are tonic and astringent. Many species of Hypericum species of H gent. Many species of Hypericum mia yield a gum-resin like Gamboge.

yield a yellow juice and an essential oil. Species of Vis-

Nat. Ord. 42.—GUTTIFERÆ or CLUSIACEÆ, the Gamboge order.—Trees or shrubs with a resinous juice, opposite coriaceous entire leaves, and occasionally unisexual flowers. Sepals and petals 2, 4, 5, 6, or 8, the former often unequal, the latter equilateral. Stamens numerous, often united. Disk fleshy. Ovary one or many-celled.; stigma usually sessile and radiate. Fruit dry or succulent, one or manycelled. Seeds exalbuminous, often immersed in pulp. Natives of humid and hot places in tropical regions, chiefly South America. The properties of the order are in general acrid and purgative. The plants yield a yellow gum re-Cambogia Gutta (Hebradendron cambogioides of Graham) is the source of Ceylon Gamboge. Different species of Garcinia yield a substance like Gamboge. Garcinia cochinchinensis has been said to be the source of the Siam Gamboge, the best commercial specimens of which are in the form of pipe Gamboge, but this is very doubtful. Garcinia elliptica, found in Sylhet and Tavoy, also supplies a kind of Gamboge. Coorg or Wynaad Gamboge is also the produce of a Garcinia, perhaps G. pictoria. Gamboge is used as a pigment and as a drastic purgative. Garcinia Mangostana, a native of Malacca, produces the Mangosteen, one of the finest known fruits. Mammea americana produces the Mammee Apple.

Nat. Ord. 43.—MARCGRAVIACEÆ, the Marcgravia order. Trees or shrubs allied to Guttiferæ, and differing chiefly in their alternate leaves, unsymmetrical flowers, and versatile anthers. Some of the plants have remarkable pitcherlike bracts. They are found in equinoctial America chiefly.

Nat. Ord. 44.—HIPPOCRATEACEE, the Hippocratea order.—Shrubby plants with opposite simple leaves having deciduous stipules. Sepals and petals five, imbricate. Stamens three, monadelphous. Fruit either consisting of three winged carpels or baccate. Brown and Lindley put the or-

Botany. determined. It has been naturalized in Europe. The rind der near Celastraceæ, notwithstanding its hypogynous sta-Botany. mens. They are principally South American plants; some occur in Africa and India. The nuts of Hippocratea comosa are oily and sweet. The fruit of Tontelea pyriformis is eaten in Sierra Leone.

Nat. Ord. 45.—Malpighia order.— Trees or shrubs, often climbing, with opposite or alternate leaves, and short deciduous, sometimes intrapetiolar, stipules; occasionally showing peltate hairs. Sepals five, combined at the base, glandular. Petals five, unguiculate. Stamens ten, often monadelphous. Ovary generally of three carpels. Fruit a drupe, a woody nut, or a samara. Seed orthotropal, suspended by a cord, exalbuminous, embryo straight or curved. Malpighiads are nearly all tropical plants. Their properties are generally astringent. Many are handsome trees or climbers with showy flowers. The wood is sometimes formed in an anomalous manner (Fig.

Nat. Ord. 46.—ERYTHROXYLACEÆ, the Erythroxylon order.—Allied to Malpighiads, and distinguished by the flowers growing from among imbricated scales, the absence of calycine glands, the presence of plaited scales at the base of the petals, and by the ovules being anatropal and cordless. They are West Indian and South American plants. Some of them have stimulating qualities, others yield a tonic bark. Erythroxylon Coca, a Peruvian plant, called Ipadú by the Indians of the Rio Negro, is famed for exciting the nervous system.

Nat. Ord. 47.—ACERACEÆ, the Maple order.—Trees with opposite, simple, often palmate, exstipulate leaves, and corymbose or racemose unsymmetrical flowers. Calyx usually of five parts. Petals as many as the sepals, or none. Stamens generally eight, inserted on or around a hypogynous disk. Ovary of two carpels, more or less united; ovules in pairs. Fruit samaroid. Seed solitary, exalbuminous; embryo coiled. Found in the temperate parts of Europe, Asia, and America. Their properties are saccharine, the trees yield light and useful timber. Acer Pseudo-platanus is the Common Sycamore or Greater Maple, which thrives well even when exposed to the sea. A. saccharinum, the Sugar-Maple, supplies the maple sugar of.America.

Nat. Ord. 48.—Sapindaceæ, the Soapwort order.— Trees, shrubs, or climbers with tendrils, rarely herbs; having alternate or opposite, usually compound leaves, and unsymmetrical, generally irrregular and polygamous flowers. Calyx with 4-5 sepals. Petals 4-5, occasionally 0, sometimes with an appendage inside. Disk fleshy. Stamens usually 8-10. Ovary 2-3-celled; style undivided, or 2-3cleft. Fruit capsular or fleshy, sometimes winged. Seeds exalbuminous, arillate; embryo usually curved. Found chiefly in the tropical parts of South America and India. The Hippocastaneae or Horse-chestnuts, distinguished by opposite leaves (Fig. 131), and two ovules in each cell, one erect, and the other suspended, occur in the north of India, Persia, and the United States. The properties are various. Many of the plants have saponaceous qualities, hence the name of the order. Some are astringent; others yield edible fruits and seeds, and not a few are poisonous. The bark of *Esculus Hippocastanum*, the Horse-chestnut, is febrifugal. *Cupania (Blighia) sapida*, furnishes the Akee fruit, with its remarkable succulent edible arillus. Nephelium (Euphoria) Litchi, supplies the Li-chi fruit of China. Ophiocaryon paradoxum is the Snake-nut-tree of Demerara. Paullinia sorbilis is the Guarana plant, the seeds of which supply an important tonic beverage in

Nat. Ord. 49.—RHIZOBOLACEÆ, the Suwarrow-nut order. -Trees with opposite, digitate, exstipulate leaves. Sepals, 5-6, more or less combined. Petals 5-8, unequal. Stamens ∞ , arising with the petals from a hypogynous disk.

Botany. Fruit of several combined indehiscent, one-seeded nuts. Seed reniform, exalbuminous, with a cord dilated into a spongy excrescence; radicle very large. Found in South America. The plants of the order are large timber trees, some of which yield edible fruit. Caryocar butyrosum (Pehea tuberculosa) is a gigantic tree of Demerara, producing the Souari, Suwarrow, or Surahwa nuts, the kernels of which are esteemed the most agreeable of all the nut kind.

Nat. Ord. 50.—Meliaceæ, the Melia order.—Trees or shrubs with alternate, exstipulate, simple or compound leaves. Sepals 3, 4, or 5, more or less united. Petals, the same number. Stamens twice as many as the petals. Disk, cuplike. Ovary, with cells varying from 3 to 12. Fruit succulent or capsular. Seeds not winged, with or without albumen; embryo with leafy cotyledons. They are chiefly tropical plants, and are found in Asia, America, and Africa. The properties of the order are bitter, astringent, and tonic. Some of the plants act as powerful purgatives and emetics. Melia Azedarachta, the Neem-tree or Pride of India, has febrifugal qualities. The pericarp yields an oil used for lamps.

Nat. Ord. 51.—HUMIRIACEÆ, the Humirium order.— Balsamic trees or shrubs, with alternate, simple, exstipulate leaves. Calyx in five divisions. Petals five, imbricate. Stamens on monadelphous; anthers two-celled, with a membranous connective beyond the lobes. Disk often present. Ovary five-celled. Fruit a drupe. Seed albuminous; embryo orthotropal. Natives of tropical America. The Balsam of Umiri is procured from Humirium floribundum,

by making incisions into its trunk.

Nat. Ord. 52.—CEDRELACEÆ, the Mahogany order.— Trees with alternate, pinnate, exstipulate leaves, allied to Meliaceæ, and chiefly distinguished by their indefinite and winged seeds. The fruit is capsular, the valves separating from a thick axis. They are common in the tropical parts of America and India. The properties of the order are fragrant, aromatic, and tonic. Many yield timber. Cedrela febrifuga has a febrifugal bark. Soymida febrifuga, the Red-wood tree, is febrifugal and astringent. Swietenia Mahagoni, the Mahogany, grows in dense forests, and forms one of the most lofty and gigantic tropical trees.

Nat. Ord. 53.—VITACEÆ or AMPELIDEÆ, the Vine order

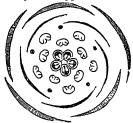

The Vine (Vitis vinifera). showing the leaves with radiating venation, the clusters of flowers, and the tendril or cirrhus, coiled up in a spiral form.

(Fig. 458).—Shrubby plants climbing by tendrils, with tumid joints, simple or compound leaves, opposite below, alternate above, and small green flowers arranged in a racemose or

umbellate manner. Calyx small, nearly entire. Petals 4-5, induplicate, inserted outside a disk, sometimes cohering at their tips, and caducous (Fig. 218). Stamens 4-5, opposite the petals, inserted on the disk (Fig. 238). Ovary usually two-celled, with two erect ovules in each cell. Fruit a uva. Seeds with a bony spermoderm; embryo small in horny The tendrils in this order are abortive branches (Fig. 72). Vineworts inhabit the milder and hotter regions of the globe. They are common in the East Indies The Grape Vine (Vitis vinifera) is said to be a native of the shores of the Caspian, whence it has been widely distributed. The plants of this order have acid leaves and a pulpy fruit more or less acid at first, but developing grapesugar as it ripens. They have frequently large dotted vessels abounding in sap, and they bleed copiously. Spiral vessels with air are common in the Vine.

Nat. Ord. 54.—GERANIACEÆ, the Cranesbill order (Fig. 459).—Herbs or shrubs, with tumid joints, opposite or al-

ternate leaves, usually palmatelyveined and lobed, often stipulate. Sepals 5, imbricate, one sometimes spurred. Petals 5, unguiculate, contorted in æsti-Stamens usually 10, monadelphous, occasionally some sterile. Ovary of five bi-ovular carpels placed round an elonone-seeded carpels, which finally separate from the base of the central axis or beak, and curve upwards by means of the attached styles (Fig. 183); the firmit is conducted. gated axis to which the styles

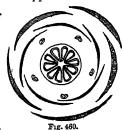

and the long beak or carpophore gives origin to the name of the order. Seed exalbuminous; embryo curved and doubled up, with plaited cotyledons. Distributed over various parts of the world. The species of *Pelargonium* abound at the Cape of Good Hope. The order has astringent and aromatic properties. Many of the plants are fragrant. Some have a musky odour.

Nat. Ord. 55.—LINACEÆ, the Flax order (Fig. 460).-Herbs with entire, sessile, alternate or opposite or verticil-

late leaves, which are exstipulate or have occasionally a pair of minute glands at their base. Flowers regular and symmetrical. Sepals 3-5, imbricate. Petals 3-5, contorted in æstivation. Stamens united at the base, 3-5, usually with intermediate abortive ones in the form of teeth opposite the petals. Ovary 3-5-celled; styles 3-5 (Fig. 278). Fruit a plurilocuar capsule, in which the cells are more or less completely divided into two by spurious divisions proceeding from the dorsal sutures. Seeds, one in each cell, anatropal, Seeds, one in each cell, anatropal,

seeds are demulcent and oilv.

with little or no albumen; embryo straight, cotyledons

flat. Distributed over various quarters of the globe, but most abundant in Europe and the north of Africa. The order is distinguished by its mucilaginous properties, and by yielding valuable fibres. Some species are purgative and diuretic. Linum catharticum,* is called Purging-flax, *Pl. CXV. from its properties. L. usitatissimum,* the cultivated Flax, fig. 1. yields tenacious fibres, used in the manufacture of linen. Its *Pl. CXV.

Nat. Ord. 56.—OXALIDACEÆ, the Wood-sorrel order (Fig. 461).—Herbaceous or shrubby plants with alternate, rarely opposite, simple or compound leaves, and regular

Botany. flowers. Sepals five, imbricate. Petals five, twisted. Stamens ten, more or less monadelphous, of different lengths. Fruit usually a five-celled capsule, sometimes drupaceous. Seeds with a fleshy outer coat, which bursts in an elastic

manner when ripe, so as to expel the seeds; embryo straight and large in thin albumen. The plants are allied to Geraniaceæ, and differ chiefly in their gyncecium. The plants of the order are met with both in hot and in temperate regions. They are very common in America and at the Cape of Good Hope. The shrubby species are confined to warm climates. The Oxalids or Wood-sorrels have generally acid properties, from the presence of oxalic acid in the form of binoxalate of Potass, which is called the salt of sorrel. Some of them have sensitive leaves. Averrhoa Bilimbi, the Blimbing of the East

Fig. 461.

Oralis Acetosella, the common Wood-sorrel, with ternate leaves, and obcordate leaflets. By some it is considered as the true Irish Shamrock.

Indies, has an acid fruit, which is used as a pickle. Oxalis crenata bears tubers which are used as potatoes. O. Deppei has fleshy roots, which are used as culinary vegetables.

Nat. Ord. 57.—Balsaminaceæ, the Balsam order (Fig.

462).—Annual succulent herbs, with simple, exstipulate leaves, and irregular flowers. Sepals five, coloured, irregular, the odd one spurred. Petals five, irregular, distinct or cohering. Stamens five. Ovary of five united carpels; stigmas sessile. Fruit, a capsule opening septifragally by five elastic valves, which become coiled up (Fig. 462). Seeds exalbuminous; embryo straight. The flowers are usually showy. The ripe capsules burst elastically when touched, so as to scatter the seeds; hence the name of Impatiens noli-me-tangere given to one of the species. plants abound in India.

Nat. Ord. 58.—Trop. EOLACE E, the Indian Cress, or Nasturtium order (Fig. 463).—Trailing or

twining herbs, with alternate, exstipulate, and peltate or palmate leaves. Calyx spurred, formed by five united sepals. Petals five, the two upper arising from the throat of the calyx, remote from the three lower unguiculate petals. Stamens usually eight, distinct. Ovary of three united, one-seeded, carpels. Fruit indehiscent,

Fig. 463. monospermal, carpidia separating from a common axis. Seeds exalbuminous, filling the cells; embryo large. They are chiefly South

American plants. The properties of the order are acridity and pungency, resembling in this respect some of the Cru-Tropæolum majus is the common Indian Cress, or garden Nasturtium, the unripe fruit of which is pickled, and used as a substitute for Capers. The roots of T. tuberosum are eaten in Peru.

Nat. Ord. 59.—LIMNANTHAGEÆ, the Limnanthes order. -The plants of this order differ from Tropæolaceæ in their regular flowers, their erect ovules, and in the tendency to Botany. adhesion between the stamens and the calyx. Probably the order should be placed among Perigynous Exogens. It contains a few North American species, which have properties similar to Indian Cresses.

Nat. Ord. 60.—PITTOSPORACEÆ, the Pittosporum order. Trees or shrubs, with alternate, simple, exstipulate leaves. Sepals and petals, 4-5, distinct, or slightly cohering. Stamens five; anthers often porose. Ovary 2-5-celled; style one. Fruit, a capsule or berry. Seeds numerous, anatropal, often covered with a resinous pulp; embryo minute, in fleshy albumen. New Holland plants chiefly. They have more or less resinous qualities. The berries of some Billardieras are eatable. In Cheiranthera linearis the anthers are thrown to one side, and have a hand-like

Nat. Ord. 61.—BrexIACEÆ, the Brexia order.—Trees. with alternate, simple, stipulate leaves, and green flowers in axillary umbels. Calyx five-parted. Petals five, contorted. Stamens five, arising from a narrow cup, with teeth between them. Style one. Fruit drupaceous, five-cornered, five-celled, rough. Seeds numerous, albuminous Madagascar plants, of which little is known.

Nat. Ord. 62.—Zygophyllaceæ, the Bean-caper and Guaiacum order (Fig. 464).—Herbs, shrubs, or trees, with

opposite, stipulate, usually pinnate, not dotted leaves. Calyx 4-5-parted, convolute. Petals unguiculate, at first minute, afterwards large, imbricate. Stamens 8-10, often arising from the back of scales. Ovary 4-5-celled. surrounded by glands or a disk; style simple. Fruit usually a capsule, 4-5angled, opening in a loculicidal manner by 4-5 valves. Seeds usually albuminous (Tribulus is exalbuminous); embryo green. Bean-capers are geembryo green. Dean-capers and some are peculiar to America; others are found in Europe India Africa, and New Hol-

land. The plants have diaphoretic and anthelmintic properties. The wood of the arborescent plants of the order is very hard and durable. Guaiacum officinale (Lignum Vitæ), a West Indian tree, supplies the resin called Guaiac, which exudes from it spontaneously and after The resin and the wood are stimulant and diaphoretic. Zygophyllum Fabago, Bean-caper, is so called on account of its flower-buds being used as substitutes for

Nat. Ord. 63.—RUTACEÆ, the Rue order (Figs 465 and

Fig. 465.

Fig. 465. Diagram of Ruta graveolens, common or garden Rue; showing five divisions of the calyx, five twisted petals, ten stamens in two rows, five divisions of the ovary with two ovules in each.

466. Flower of Rue, showing the hooded petals, the stamens, the hypogynous punctated disk, and the ovary with its carpels; the flower being pentamerous.

466).—Herbs, shrubs, and trees, with exstipulate dotted leaves and perfect flowers. Calyx in 4-5 divisions. Petals 4-5, occasionally 0. Stamens, as many, or twice, or thrice as many, as the petals, placed outside a hypogynous disk. Ovary, sessile or stalked, 3-5-lobed; styles united, occasionally separated at the base. Fruit of several car-

Botany.

Botany. pels, either combined, or more or less distinct, often separating when ripe, and dehiscing by one or both sutures. Seeds, one or two in each carpel; the true Ruteæ (European plants) have albuminous seeds, while the Diosmeæ (from the Cape and New Holland) have exalbuminous seeds. The plants are found in Europe, Cape of Good Hope, New Holland, and America. The order is characterized by its peculiar penetrating odour. The plants are employed medicinally as antispasmodics, tonics, and febrifuges. leaves of Correa alba are used in Australia for tea. Dictamnus Fraxinella, False Dittany, abounds in volatile oil. Diosmas are the Bucku or Buchu plants found at the Cape of Good Hope, which are remarkable for their overpowering and penetrating odour, owing to the presence of a yellowish volatile oil. Galipea officinalis furnishes a tonic, febrifugal bark called Angustura. Ruta graveolens, common Rue, has antispasmodic properties.

Nat. Ord. 64.—XANTHOXYLACEÆ, the Prickly-Ash order. -Trees or shrubs, with exstipulate, dotted leaves, resembling the Rutaceæ, and distinguished by their polygamous flowers. They are chiefly found in tropical America. They have pungent and aromatic qualities, and have been used medicinally as stimulants, sialagogues, and tonics. They yield a volatile oil, and a bitter principle called Xanthopicrine.

Nat. Ord. 65.—OCHNACEÆ, the Ochna order.—A small group of undershrubs or trees allied to Rutaceæ, and distinguished by their simple, dotless, stipulate leaves, and their enlarged fleshy gynobase or torus. They are found in the tropical parts of India, Africa, and America. The order is characterized by bitter, tonic properties. The plants want the aromatic qualities of the Rueworts.

Nat. Ord. 66.—SIMARUBACEÆ, the Quassia order (Fig. 467). - Trees or shrubs, with alternate, exstipulate, dotless, usually compound leaves. Calyx in four or five divisions. Petals 4-5, imbricated. Stamens 8-10, arising from the back of hypogynous scales. Ovary 4-5-lobed, stipitate; style simple. Fruit, consisting of 4-5 drupes arranged around a common receptacle. Seeds, one in each drupe, pendulous, anatropal, exalbuminous. Natives chiefly of the tropical parts of India, America, and Africa. Bitterness prevails in this order, the plants being used as tonics. Picrasma (Picræna) excelsa, Bitterwood, is a large tree, the wood of which is the common Quassia of the shops. It is bitter and tonic, and is sometimes used as a substitute for hops. Quassia amara, (Fig. 467) the true Quassia plant, is a tall shrub found in Surinam, having

Fig. 467. Fig. 467.

with a simple style.

pinnate leaves with winged petioles. Simaba Cedron is a tree of New Grenada, which has long been celebrated as an antidote to snake bites. The bark of the root of Simaruba amara or officinalis is used as a substitute for Quassia.

Note.—Apetalous species occur in the following Thalamifloral orders:—Ranunculaceæ, Menispermaceæ, Papaveraceæ, Flacourtiaceæ, Caryophyllaceæ, Sterculiaceæ, Byttneriaceæ, Tiliaceæ, Malpighiaceæ, Geraniaceæ, Rutaceæ, Xanthoxylaceæ. Some species belonging to the orders Anonacem and Rutacem are Gamopetalous.

SUB-CLASS II.—CALYCIFLORÆ.

1. Polypetalæ, or Dialypetalæ.

Nat. Ord. 67.—Stackhousiaceæ, the Stackhousia order. -Herbs, occasionally shrubs, with simple, alternate, stipulate leaves. Calyx five-cleft, tube inflated. Petals five,

arising from the top of the calycine tube, claws united. Stamens five, distinct, perigynous. Styles 3-5. Fruit of 3-5 monospermal, indehiscent carpels, with a central column. Seed anatropal, albuminous. The order contains a few New Holland plants.

Nat. Ord. 68.—Celastraceæ, the Spindle-tree order. —Shrubs or trees, with alternate, rarely opposite, simple, stipulate leaves. Sepals and petals 4-5, imbricate. Stamens 4-5, inserted on a large disk which surrounds the ovary. Fruit superior, 2-5-celled capsular or drupaceous. Seeds usually arillate, albuminous, with a large straight embryo. Chiefly natives of the warm parts of Europe, North America, and Asia; also of the Cape of Good Hope. The order is more or less acrid, and some of the plants yield oil. Catha edulis is the Kat or Khât of the Arabs, the leaves of which are stimulant. Celastrus scandens has a purgative and emetic bark. Euonymus europæus, the common Spindle-tree, has a beautiful scarlet arillode.

Nat. Ord. 69.—STAPHYLEAGEÆ, the Bladder-nut order. -Shrubs allied to Spindle-trees, and distinguished by their compound leaves, with stipules and stipels, more or less separate carpels, and a bony spermoderm. Some consider them as having hypogynous stamens, and place them near Sapindaceæ. They are scattered over the globe. They receive the name of Bladder-nut from the membranous inflated fruit of some species, such as Staphylea pinnata-Their bark is often bitter, while their seeds are oily and

Nat. Ord. 70.—CHAILLETIACEÆ, the Chailletia order.— Trees or shrubs with alternate stipulate leaves. Calyx 5parted; æstivation induplicato-valvate. Petals five, alternate with the divisions of the calyx, sometimes united; stamens five, with glands at their base. Ovary superior, 2-3-celled; ovules two, pendulous. Fruit 1-3-celled, dry. Seeds solitary, exalbuminous. Natives of tropical America and Africa, and of the East Indies. Chailletia toxicaria has a poisonous fruit called Ratsbane in Sierra Leone.

Nat. Ord. 71.—RHAMNACEÆ, the Buckthorn order.-Shrubs or trees, often spinose, with simple, alternate leaves, and small flowers. Calyx 4-5-cleft, valvate. Petals 4-5, cucullate or convolute, inserted on the throat of the calvx. sometimes 0. Stamens 4-5, opposite the petals. Ovary sometimes adherent to the calycine tube, immersed in a fleshy disk; ovules solitary. Fruit a capsule, berry, or drupe. Seeds erect, albuminous, not arillate. Generally distributed. The properties of the order are usually acrid and purgative. Some are bitter, tonic, and astringent; others yield dyes. The fruit of some is edible. Hovenia dulcis is remarkable for the enlargement of its peduncles, which become succulent, and are used as a fruit in China. Rhamnus, Buckthorn, is the type of the order. R. ca tharticus yields a cathartic fruit. Jujube paste is pre pared from the fruit of Zizyphus Jujuba and vulgaris. Z. Lotus is the Lote-bush, the fruit of which is used by the

Nat. Ord. 72.—Anacardiace E, the Cashew order (Fig. 468).—Trees or shrubs, with alternate, exstipulate, dotless leaves, and small, sometimes unisexual, flowers. Sepals 3-5, united. Petals 3-5, imbricate. Stamens equal in number to the petals, and alternate with them, or twice as many or more, perigynous or attached to a disk. Ovary one-celled; styles and stigmas usually three; ovule solitary, with a long curved cord attached to a basal placenta. Fruit indehiscent, a nut or drupe. Seed exalbuminous; embryo curved. The order forms a part of the Terebinthaceæ of Jussieu.

Fig. 468.

Diagram of the flower of the slower of the cally, five imbricate petals, five alternating stamens, a one-colled ovary, with a solitary ovule. of the Terebinthaceæ of Jussieu. Chiefly found in tropical America, Africa, and India.

Fig. 468.

* Plate

CXVII.

poisonous juice, which often becomes black in drying. The fruit, however, in some cases is eatable. Anacardium * Pl.CXVI. occidentale, the Cashew-nut, * has a fleshy edible peduncle supporting a nut, the kernel of which can be eaten, while the pericarp is acrid. Mangifera indica produces the Mango, a highly valued tropical drupaceous fruit. Pistacia Lentiscus and atlantica yield the resin called Mastich. P. Terebinthus, the Terebinth-tree, is the source of Chian turpentine. P. vera produces the Pistachio nut. Rhus Toxicodendron, the Poison-oak, has been used as a remedy in paralysis. R. Cotinus, Venetian Sumach, often produces hairs in place of flower-stalks (Fig 158), and is called the Wigtree. Its wood is known as young fustic.

Nat. Ord. 73.—AMYRIDACEÆ, the Myrrh order.—Trees or shrubs, with alternate or opposite compound, occasionally stipulate and dotted leaves. Calyx 2-5-divided. Petals 3-5, valvate. Stamens twice as many as the petals. Ovary 1-5celled, surrounded by an annular disk; ovules in pairs; placenta apicilar. Fruit 1-5-celled, hard and dry; exocarp splitting into valves. Seeds anatropal, exalbuminous. Some consider the order as allied to Aurantiaceæ. Natives of tropical India, Africa, and America. The order abounds in balsamic resin. Some of the plants are bitter, others poisonous. Amyris hexandra and A. Plumieri are two of the sources whence Elemi is procured. Balsamodendron Myrrha, or an allied species, appears to be the source of the Myrrh of commerce, which is an aromatic, bitter gum-resin, containing volatile oil. Boswellia thurifera (serrata) and B. glabra supply Olibanum.

Nat. Ord. 74.—CONNARACEÆ, the Connarus order.— Trees or shrubs with alternate, compound, dotless, and usually exstipulate leaves. Calyx 5-parted, imbricate. Petals 5, usually imbricate. Stamens 10, perigynous or hypogynous, opposite the petals, usually united. Carpels one or more; style terminal; ovules 2, orthotropal. Fruit follicular. Seeds with or without albumen, often arillate. Tropical American plants. The aril of some Omphalobiums is eaten, and Zebra-wood is furnished by O. Lamberti.

Nat. Ord. 75.—Leguminosæ or Fabaceæ,* the Leguminous order (Figs. 469 to

471).—Herbs, shrubs, or trees, with alternate, usually compound, stipulate leaves (Figs. 129, 130). Calyx 5-divided, hypogynous, odd segment inferior (anterior). Petals. usually five, sometimes one or usually five, sometimes one or more abortive, papilionaceous (Figs. 221 and 222), or regular, odd petal (if any) superior (posterior). Stamens definite or indefinite, perigynous, rarely hypogynous, distinct or more than 10 mitted in the control of the calify with the odd segment anterior, five irregular petals, consisting of vexillum, two alse and carine, the odd petal being posterior, ten stamens, diadelphous, and a one-celled overy, which becomes the legume in fruit.

united in one or more bundles (Figs. 470). Ovary superior, one-celled, one or many-seeded, sometimes consisting

Fig. 470. Fig. 471. Fig. 470. Section of the flower of Lathyrus, showing the essential organs inclosed in the carina, and the verillum above.

471. Flower of Cercis Siliquastrum, Judas-tree, showing the vexillum or upper petal interior, as in the sub-order Casalpinies.

of one carpel (Fig. 272), sometimes of two or five. Style and stigma simple. Fruit a legume (Fig. 274), or a drupe. Seeds with or without albumen; embryo with large coty-

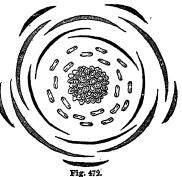

Botany. The plants abound in a resinous, or milky, acrid, and ledons (Fig. 61). The order is a very extensive one, and Bot the plants belonging to it are found in all parts of the world. They are most abundant in warm regions, and diminish on approaching the poles. Leguminous plants have been divided into three sub-orders.—Sub-order 1. Papilionaceæ, petals papilionaceous, imbricate, upper one exterior (Fig. 221). Sub-order 2. Cæsalpineæ, petals imbricated, upper one interior (Fig. 471). Sub-order 3. Mimoseæ, petals valvate in æstivation.

The properties of the order are very various. Some are nutritious, others tonic and astringent, others purgative, and some poisonous. The plants supply timber, fibres, gums, dyes, and various other economical articles. Among the plants of the order may be noticed Beans, Peas, Lentils, Kidney-beans, and Pulse of various kinds, Lupins, Clover, Lucerne, Medick, Saintfoin, Liquorice, Tragacanth, Indigo, Kino. The greater number are more or less nutritious or wholesome. There are, however, some poisonous plants, as *Coronilla varia*, the seeds and bark of Laburnum, the Calabar bean, and others. Eschynomene paludosa supplies Indian Rice-paper, the Shola of India. Astragalus gummifer, verus, and other species, furnish Gum Tragacanth. Butea frondosa, the Dhak-tree or Pulas of India, yields a kind of Kino. Glycyrrhiza glabra supplies Liquorice-root. Indigofera tinctoria, and I. carulea, supply the Indigo of commerce. The Legumes of Mucuna pru-riens and prurita, Cowitch, are covered with irritating hairs, which are used mixed with syrup as a vermifuge. Myrospermum peruiferum yields the Balsam of Peru, and M. toluiferum that of Tolu. Pterocarpus Marsupium, an Indian tree, is the source of Malabar Kino. Cæsalpinia brasiliensis furnishes the Brazil-wood. Divi-divi, or Libi-divi, is the twisted legumes of C. coriaria, which are used in tanning. Species of Cassia, such as C. acutifolia, lanceolata, elongata, and obovata, furnish the various kinds of Senna. Ceratonia Siliqua, the Algaroba-bean or Carob-tree, has an edible legume, which is used as food for horses. Various species of Copaifera yield the West Indian and Brazilian Balsam of Copaiva. Hamatoxylon campechianum, the Logwood-tree, is used as a dye. Tamarindus indica, the Tamarind-tree, contains in its pod a laxative pulp, which is a secretion from the endocarp. Various species of Acacia, such as A. Ehrenbergii, tortilis, vera, and arabica, yield Gum Arabic and Gum Senegal.

Nat. Ord. 76.—MORINGACEÆ, the Moringa order.—This order is considered as allied to Leguminosæ, the plants differing chiefly in their petaloid sepals, stamens arising from a perigynous disk, a pod-like capsular fruit with three valves, three parietal placentas, and loculicidal dehiscence, with the seeds buried in the substance of the valves. Trees with pinnate or tripinnate leaves, found in the East Indies and in Arabia. The properties of the order are usually stimulant

and pungent. Some species yield a fragrant. oil. Moringa pterygosperma, Horse - radish tree, has winged seeds. Its root has the taste of Horse-radish, and its seeds are called Ben - nuts, supplying Ben-oil, used by perfumers and watchmakers.

Nat. Ord. 77.-Ro-SACEÆ, the Rose order (Figs. 472 to 474).—

Trees, shrubs, or herbs, biagram of the flower of the Strawberry, showing five outer calycine segments (epicalyx) five inner segments, odd one superior, tive petals, numerous stamens and carpels.

regular, rarely unisexual, flowers. Calyx 4-5-lobed, sometimes calvculate, fifth lobe posterior. Petals 5 (Fig. 220), Botany. rare y O. Stamens definite or indefinite. Disk lining the tube of the calyx, or surrounding its orifice. Ovaries

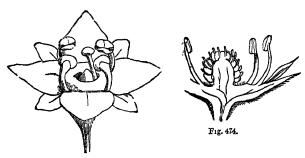

Fig. 473.

Fig. 473. Flower of Alchemilla with a double tetramerous calyx, 4 stamens, and a basilar style.

... 474. Flower of the Strawberry cut vertically, showing calyx, petals, stamens attached to the calyx, numerous one-seeded carpels on an elevated receptacle.

solitary or several, one-celled, with one or few anatropal ovules. Styles lateral (Figs. 288, 473), or terminal. Fruit achenes (Fig. 474), drupes (Fig. 302), follicles (Fig. 273), or pomes (Fig. 325). Seeds one or more, exalbuminous, with a straight embryo having flat cotyledons. This order is generally distributed over the globe, but the species are most abundant in temperate climates, where they supply many important fruits. The following are the divisions of the order: -Sub-order 1. Chrysobalaneæ, trees or shrubs, carpel solitary, cohering more or less to one side of the calvx, ovules two, erect, style basilar, fruit a drupe, stipules not united to the petiole. Ex. Chrysobalanus. Sub-order 2. Amygdaleæ, or Drupiferæ, trees or shrubs, with a deciduous calyx-tube, carpel solitary, free, style terminal, fruit a drupe, stipules not united to the petiole. Ex. Amygdalus, Prunus. Sub-order 3. Roseæ, herbs and shrubs, carpels not adhering to the tube of the calyx, styles terminal or lateral, fruit achenes or follicles, stipules united to the petiole. Under this sub-order there are four tribes:—Tribe I. Spiræidæ, fruit a whorl of follicles, not inclosed within the calycine tube (Fig. 273). Ex. Spiræa. Tribe 2. Potentillidæ (Dryadeæ of some), calyx-tube short or nearly flat, not inclosing the fruit; fruit achenes or drupes (acini), five or more, upon a flat or convex receptacle (Fig. 474 and 184). Ex. Rubus, Fragaria, Potentilla. Tribe 3. Sanguisorbidæ, achenes 1-2, inclosed within the dry calyx-tube, petals often 0 (Fig. 473). Ex. Alchemilla. Tribe 4. Rosidæ, achenes numerous, inclosed within the fleshy calycine tribe, which is contracted at the orifice (Fig. 185). Ex. Rosa. Suborder 3. Pomeæ, trees or shrubs, carpels 1-5, adhering more or less to the tube of the calvx and to each other; fruit a pome; stipules not united to the petiole (Fig. 325). Ex. Pyrus.

Astringent properties are exhibited by the bark and root of most of the plants of the order. Prussic acid occurs in the sub-orders Amygdaleæ and Pomeæ. Many of the plants supply edible fruits, such as the Apple, Pear, Quince, Medlar, Loquat, Plum, Cherry, Peach. Chrysobalanus Icaco, the Cocoa-plum, is a West Indian stonefruit. Amygdalus communis, the Almond-tree, is a native of Asia and Barbary, and is cultivated extensively to the south of Europe. There are two varieties, -one producing sweet, and the other bitter almonds. The kernels of the former contain a fixed oil and emulsine, while those of the latter contain in addition a nitrogenous substance called Amygdaline, which, by combination with emulsine, produces a volatile oil and Prussic acid. Cerasus Laurocerasus, Cherry-laurel, or common Bay-laurel, yields a hydrocyanated oil. Prunus communis is the source of the common Plum. Brayera anthelmintica, Cusso or Kousso, an Abyssinian plant, is used as a vermifuge. Rosa centifolia, the common Cabbage-rose, and its varieties R. damascena and R. moschata, yield a fragrant essential oil, called Attar of Roses, which is distilled from the petals.

Nat. Ord. 78.—CALYCANTHACEÆ, the Calycanthus order.—Shrubs with quadrangular stems, having four woody axes surrounding the central one, opposite, entire, exstipulate leaves, and solitary lurid flowers. Calyx of numerous coloured sepals confounded with the petals, and all united below into a fleshy tube, bearing numerous stamens on its rim. Outer stamens extrorse; inner, sterile. Ovaries several, one-celled, adherent to the calycine tube; ovules one or two. Fruit, achænia inclosed by the calyx. Seed exalbuminous; cotyledons convolute. The plants are found in North America and Japan. Their flowers have an aromatic fragrance, and their bark is sometimes used as a carminative. Calycanthus floridus, Carolina Allspice, furnishes a bark which is sometimes used in place of Cinnamon.

Nat. Ord. 79.—LYTHRACEÆ, the Loosestrife order.—Herbs, rarely shrubs, often with quadrangular branches, with usually opposite, and entire exstipulate leaves. Among the allied exalbuminous perigynous orders it is distinguished by its tubular calyx inclosing a 2-6-celled ovary which is free from it, its united styles, membranous capsular fruit, and stamens inserted on the calycine tube below the petals. The plants are chiefly tropical; some are found in Europe and in North America. Astringency is met with in many plants of the order. Some of them furnish dyes. Lawsonia inermis is the Henna or Alkanna of Cyprus and Egypt, which is used in the East for dyeing the nails, the palms of the hand, and the soles of the feet, of an iron-rust colour.

Nat. Ord. 80.—Rhizophoraceæ, the Mangrove order.—Trees or shrubs, with simple, opposite leaves, having deciduous interpetiolary stipules. Calyx adherent, with 4-12 valvate lobes. Petals 4-12. Stamens twice or thrice as many. Ovary 2-4-celled, with 2 pendulous ovules in each cell. Fruit monospermal, indehiscent, crowned by the calyx. Seed exalbuminous; embryo germinating in the pericarp. The plants grow in the unhealthy maritime swamps of the tropics. Mangroves have usually astringent barks, employed as febrifuges and for tanning. Some are used for dyeing black. *Rhizophora Mangle*, the Mangrove tree (Fig. 67), has remarkable aerial roots. Its bark is used for tanning.

Nat. Ord. 81.—Vochyslaceæ, the Vochysla order.— Trees or shrubs, with their young branches often quadrangular, leaves entire, usually opposite and stipulate. Sepals 4-5, upper one spurred. Petals 1-5, unequal. Stamens 1-5. Fruit a triquetrous, 3-celled capsule, with a central placenta. Seeds exalbuminous, usually winged. Found in equinoctial America. Some of the plants are timber trees.

Nat. Ord. 82.—Combretaces, the Myrobalan order.—Trees or shrubs, with alternate or opposite, entire, exstipulate leaves, often apetalous. They are distinguished from the orders near them by their one-celled ovary, containing 2-4 suspended ovules, but only a single seed in the fruit, and convolute cotyledons. Natives of tropical regions. The plants of this order have astringent properties. Some species are cultivated for ornament; others yield timber. Terminalia belerica, and T. Chebula, yield the astringent fruit known by the name of Myrobalans.

Nat. Ord. 83.—MELASTOMACEM, the Melastoma order.—Trees, shrubs, or herbs, with opposite, ribbed leaves, and showy flowers. The anthers are long, rostrate, and bent down parallel to the filaments in æstivation, lying in spaces between the calyx and ovary. The plants differ from Lythraceæ in the calyx-lobes not being valvate, and from Myrtaceæ in the leaves not being dotted. Memecylon has sometimes been made the type of a separate order on account of its adherent calyx, ribless leaves, and convolute cotyledons. The plants of this order are chiefly tropical. They possess

edible fruits. None are poisonous. Nat. Ord. 84.—Alangiace, the Alangiam order.— Trees or shrubs, with branches often spiny, leaves entire, alternate, exstipulate, and without dots. Čalyx adherent, 5-10-toothed. Petals 5-10, linear, reflexed. Stamens equal in number to the petals, or two or four times as many; filaments villous at the base; anthers adnate, linear. Fruit a drupe adherent to the calyx. Seed anatropal, pendulous, albuminous; cotyledons flat. Natives of India and North America. Many of the plants supply timber; others have edible fruits. Some are aromatic.

Nat. Ord. 85.—PHILADELPHACEÆ, the Syringa order.-Shrubs, with opposite, deciduous, exstipulate, dotless leaves. Calyx adherent, 4-10-lobed, valvate. Petals alternate with the calycine segments. Stamens indefinite. Styles distinct or united. Fruit a half-inferior 4-10-celled capsule, with an axile placenta. Seeds albuminous. The species are scattered over Europe, North America, and India. The flowers of *Philadelphus coronarius*, common garden Syringa, have an overpowering odour, and yield an oil. It is called Mock Orange in America. The leaves of the plant taste like Cucumbers. The leaves of the species of *Deutzia*, especially D. scabra, are covered with beautiful star-like hairs or scales.

Nat. Ord. 86.—MYRTACEÆ, the Myrtle order (Fig. 475). Trees or shrubs, with entire, exstipulate, usually opposite and dotted leaves, often having an intramarginal vein. Calyx adherent (Fig. 476), cleft, sometimes operculate. Petals

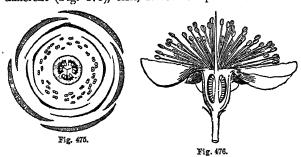

Fig. 475. Diagram of the flower of Myrtus, showing five segments of the calyx, five petals with quincuncial estivation, numerous stamens, a three-celled ovary with seeds attached to a central placents.

... 476. Flower of the Myrtle cut vertically, showing adherent calyx, separate petals, numerous stamens inserted into the calyx, inferior ovary with ovules and a simple style.

4-5, sometimes none. Stamens usually ∞ with long filaments and ovate anthers. Style simple. Fruit baccate in true Myrteæ and capsular in Leptospermeæ. Seeds usually numerous, exalbuminous. Tropical and sub-tropical plants. The plants of this order are generally aromatic, and yield a pungent volatile oil. Some of them are astringent, others yield gummy and saccharine matter. The unexpanded flower-buds of Caryophyllus aromaticus constitute the Cloves of commerce. Eugenia Pimenta bears an aromatic fruit. having the flavour of Cloves, Cinnamon, and Nutmeg, and which, when dried, constitutes Allspice, Pimento, or Jamaica Pepper. The leaves of Melaleuca minor furnish the green pungent oil of Cajeput. Species of Psidium supply the fruit called the Guava. Punica Granatum yields the Pomegra-

Nat. Ord. 87.—CHAMÆLAUCIACEÆ, the Fringe-Myrtle order.—Small heath-like bushes, with evergreen leaves abounding in oil. Allied to Myrtaceæ, but differing in their fringed or feathery calyx, sterile staminal row, and 1-celled ovary. They are fragrant New Holland plants.

Nat. Ord. 88.—LECYTHIDACEÆ, the Monkey-pot order. -Large trees, with stipulate leaves and showy flowers. Allied to Myrtaceæ, but distinguished by their large almondlike seeds, their alternate, dotless leaves, and by their stamens being in part collected into a hooded plate. The fruit

Botany. a slight degree of astringency. Some yield dyes, others is a woody capsule, often with circumscissile dehiscence Botany. (Fig. 311). Natives of the warm regions of South America. Many of the plants yield edible seeds. Their seed-vessels are sometimes used as cups and bowls, and their wood is put to economic uses. The seeds of Bertholletia excelsa are the Brazil or Castanha nuts of the shops. Lecythis ollaria is one of the largest trees in the Brazilian forests. Its seed-vessel receives the name of Monkey-pot-

seeds are called Sapucaya nuts.
Nat. Ord. 89.—Barringtoniaceæ, the Barringtonia order.-Trees or shrubs referred by most authors to the Myrtle alliance, but distinguished by the presence of a large quantity of albumen, alternate, dotless, and often serrated leaves. The fruit is pulpy. Natives of the tropics. The bark of some of the plants is bitter and tonic.

Nat. Ord. 90.—Onagrace E, the Evening-Primrose order

(Fig. 477).—Herbs or shrubs, with alternate or opposite, simple, exstipulate, dotless leaves, and showy tetramerous flowers. Calyx superior, tubular, limb 4-lobed, valvate. Petals usually 4, twisted in æstivation. Stamens epigynous, generally 4 or 8; pollen triangular (Fig. 269). Ovary 2-4-celled; styles united; stigma capitate or 4-lobed. Fruit capsular or baccate. Seeds exalbuminous. Chiefly natives of the temperate parts of America. The plants of this order have mucilaginous and astringent properties. Some yield edible roots and fruits. Fuchsia is remarkable for its coloured calvx and succulent subacid fruit. Enothera, Evening Primrose, is so called, because many of the species open their flowers at night.

Nat. Ord. 91.—HALORAGEACEÆ, the Hippuris or Mare's-tail order.—Herbs or undershrubs, often aquatic, with alternate, opposite, or whorled leaves, and small, frequently incomplete flowers. They may be regarded as an imperfect. form of Onagraceæ, from which they are distinguished by their minute calyx, and their solitary pendulous seeds. They are frequently apetalous, and the stamens are sometimes reduced to one. They are found in all quarters of the globe. Some of the plants of the order yield edible form of Onagraceæ, from which they are

seeds; others have a fragrant odour. Trapa natans, the Water-Chestnut, furnishes edible seeds. T. bicornis has a remarkable horned fruit like the head of a bull.

Nat. Ord. 92.—Loasaceæ, the Loasa or Chili-Nettle order.—Herbs with rigid or stinging hairs, opposite or al-

ternate, exstipulate leaves, and showy flowers. Calyx adherent, limb 4-5parted. Petals 5 or 10, often cucullate. Stamens on, distinct or united in bundles. Ovary 1-celled, with several parietal placentas; style single. Fruit capsular or succulent. Seeds albuminous. American plants, some of which receive the name of Chili-Nettles on account of the stinging property of their hairs.

Nat. Ord. 93.—Cucurbitaceæ, the Gourd order (Figs. 478 to 480).—Succulent climbing plants, with extra-axillary tendrils (in place of stipules), alternate, palmately-veined, scabrous leaves, and unisexual flowers. Calyx adherent, limb 5-toothed or obsolete.

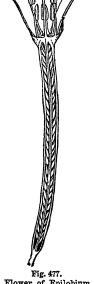

Fig. 478.

Diagram of the male flower of the Melon, showing five divisions of the callyx, five imbricate segments of the corolla, five stamens with sinuous an Ners, four of the stamens being united in pairs, and the fifth one free; in the centre is seen the abortive ovary.

Petals 4-5 usually

Botany.

Botany. united, reticulated. Stamens generally 5, distinct or combined; anthers long and sinuous. Ovary 1-celled, inferior. with 3 parietal placentas; stigmas thick, dilated or fringed. Fruit a pepo (Fig. 324). Seeds flat, exalbuminous; cotyledons leafy. Chiefly natives of hot countries; they abound in India and South America. The plants of the order may be said in general to possess a certain degree of acridity, which is sometimes so marked as to give rise to drastic purgative qualities. In many cases, however, as in the Melon, the Cucumber, the Vegetable Marrow, Gourd, Pumpkin, and Squash, the fruit is edible when cultivated. The seeds are usually harmless. Bryonia alba and B. dioica have large roots, which are powerful purgatives. Citrullus (Cucumis) Colocynthis, Coloquintida, or Bitter Apple (Fig. 480),

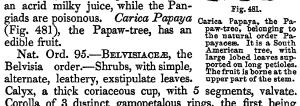

Fig. 479. Diagram of the female flower of the Melon, showing a similar arrangement of the floral envelopes, as in fig. 478, an abortive circle of stamens, and the ovary, with three parietal curved placentaries sending processes towards the centre.
480. Citrullus or Cucumis Colceynthis, the Colceynth plant, with its palmately-veined leaves, cirrhose stipules on one side of the leaf, and a pulpy fruit or Pepo.

has a round fruit, the pulp of which is the Colocynth of the shops. Cucumis sativus, yields the common Cucumber; C. Melo, the Common Melon; Cucurbita Citrullus, the Water Melon, and C. ovifera, Vegetable Marrow. Echalium purgans (Momordica Elaterium), is called Squirting Cucumber, on account of the elastic mode in which its seeds are scattered. The feculence deposited from the juice of the fruit constitutes the hydragogue cathartic called Ela-

Plate figs. 1—5. Nat. Ord. 94.—PAPAYACEÆ, the Papaw order (Fig.

481).—Trees or shrubs often having an acrid milky juice, with alternate, lobed, long-petioled leaves, and unisexual flowers. The plants are distinguished from Cucurbitaceæ by not climbing, and by having a free ovary with 5 placentas and albuminous seeds. The natural order Pangiaceæ may be included, which differs only in having a polypetalous corolla and scales attached to the throat of the female flower. Papayaceæ are chiefly found in South America; Pangiaceæ in India. Many of the Papaw-worts have an acrid milky juice, while the Pan-

Calyx, a thick coriaceous cup, with 5 segments, valvate. Corolla of 3 distinct gamopetalous rings, the first being large and conspicuous, and consisting of 5 lobes, each with 7 ribs and 7 teeth, the second being a narrow membrane cut into sharp pointed segments, the third being an inconspicuous membranous cup finely cut. Stamens 20, in an erect cup-like form, unequally united. Disk fleshy, cuplike, covering the ovary, and standing as high as the stigma.

Ovary 5-celled; ovules 2 in each cell, suspended from an axile placenta; style and stigma pentagonal. Fruit a large round berry crowned by the calyx. Seeds large and reniform. Natives of tropical Africa. The pulp of the fruit is eatable, and the rind contains so much tannin as to be used for making ink; the wood is soft, and contains numerous dotted vessels. Bentham considers the order as a section of Myrtaceæ, while Lindley considers it as allied to Rhizophoraceæ.

Nat. Ord. 96.—Passifloraceæ, the Passion-flower order.—Herbs or shrubs usually climbing by tendrils, with alternate, stipulate, sometimes glandular leaves. Calyx of 5 sepals, united below, the throat bearing 5 petals and filamentous or annular processes. Stamens 5, monadelphous, surrounding the gynophore; anthers extrorse. Ovary free from the calyx, 1-celled; styles 3, club-shaped. Fruit mostly fleshy, stalked, 1-celled, with 3 parietal polyspermous placentas. Seeds albuminous, arillate. They are common in tropical America. Astringent and narcotic qualities appear to prevail in the order. Many of the species, however, produce edible fruits. Passiflora quadrangularis produces the granadilla, a well-known West Indian

Nat. Ord. 97.—Homaliaceæ, the Homalium order.— Trees or shrubs with alternate leaves with or without stipules. Calyx infundibuliform, with 5-15 divisions. Petals equal in number to the segments of the calyx and alternate with them. Stamens arising from the base of the petals, either singly or in bundles of 3 or 6. Ovary adherent, 1-celled; ovules numerous, pendulous; placentas 3-5, parietal; styles 3-5. Fruit a capsule or berry. Seeds albuminous. Tropical plants of India, Africa, and America, having astringent properties.

Nat. Ord. 98.—TURNERACEÆ, the Turnera order.— Herbs, sometimes shrubby plants, having a Cistus-like habit, with alternate, exstipulate, pubescent leaves. Calyx 5-lobed, bearing 5 petals and 5 stamens. Ovary free, 1-celled, with 3 parietal placentas and 3 styles which are often forked or multifid at the apex. Fruit a 3-valved capsule. Seeds albuminous, strophiolate at one side. The plants have astringent, tonic, and occasionally aromatic qualities, and are natives of South America and the West Indies.

Nat. Ord. 99.—PORTULACACEÆ, the Purslane order.— Succulent herbs or shrubs, with alternate or opposite, entire, exstipulate leaves. Calyx of 2 coherent sepals. Petals 5. Stamens variable in number, sometimes opposite the petals; anthers versatile. Ovary 1-celled, formed of 3 united carpels. Fruit capsular, usually dehiscent by valves or by a lid. Seeds numerous, albuminous, attached to a central placenta; embryo peripherical. This order has the stamens sometimes hypogynous, and it has been placed near Caryophyllaceæ by some authors. The plants are found in dry places, in various parts of the world, more particularly in South America and at the Cape of Good Hope. Esculent and antiscorbutic qualities prevail in the order. Some have showy flowers which are ephemeral.

Nat. Ord. 100.—ILLEGEBRACEÆ or PARONYCHIACEÆ, the Knotwort order.-Herbaceous or suffruticose plants, with opposite or alternate, often clustered, sessile, entire, stipulate leaves, and minute flowers. Sepals 3-5, distinct or cohering. Petals small, sometimes 0. Stamens opposite the sepals, if equal to them in number. Ovary superior; styles 2-5. Fruit dry, 1-3-celled, indehiscent or opening by 3 valves. Seeds either numerous and attached to a free axile placenta, or solitary and pendulous from a cord attached to a basal placenta. Seeds albuminous; em bryo curved. This order is by some placed near Caryophyllaceæ, from which it differs in the presence of scarious stipules and in its perigynous stamens. The plants are

Botany. natives chiefly of barren places in the south of Europe and Ovary 1-celled, with parietal placentas; style single; Botany. north of Africa, and their properties are astringent.

Nat. Ord. 101.—CRASSULACEÆ, the Stonecrop order (Fig. 482 and Fig. 217).—Succulent herbs or shrubs, with exstipulate leaves and cymose, often secund flowers. Sepals 3-20, more or less combined. Petals 3-20, separate or united. Stamens equal in number to the petals, or twice as many. Carpels 1-celled, of the same number as the petals, having hypogynous scales at their base. Fruit follicular. Seeds numerous, albuminous. Natives of dry places in all parts of the world.

The many plants of the world.

The provide in many plants of Acridity prevails in many plants of

Fig. 482.

this order. Some species are refrigerant, others astringent. Bryophyllum calycinum has a gamopetalous corolla, and produces marginal buds on its leaves (Fig. 141). Sedum Telephium has been employed in diarrhoea as an astringent. S. acre, Biting Stonecrop, possesses acridity, and has emetic

and purgative properties.

Nat. Ord. 102.—Mesembryanthemaceæ or Ficoideæ, the Fig-Marigold order.-Succulent shrubs or herbs, with opposite simple leaves and often showy flowers. Sepals 4-8, more or less united. Petals and stamens ∞. Capsule usually many-celled, opening in a stellate manner; placenta central or parietal. Seeds numerous, albuminous; embryo curved or spiral. Natives of the hot sandy plains of the Cape of Good Hope; a few also are found in Europe, South America, and China. Some of the plants are esculent, others furnish alkaline matter, while a few are diuretic. Mesembryanthemum crystallinum is called the Ice-plant, on account of the watery vesicles on its surface.

Nat. Ord. 103.—Tetragoniaceæ, the Tetragonia order. -Succulent plants nearly allied to Fig-Marigolds, but differing in the want of petals and in having definite stamens. The fruit is either an indehiscent nut or a pyxidium. They are found in the South Sea Islands, the Mediterranean, and the Cape of Good Hope. Many of them are saline, others are esculent. Tetragonia expansa is used as Spinage in New Zealand.

Nat. Ord. 104.—CACTACEÆ, the Cactus order (Figs.

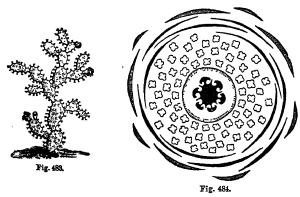

Fig. 483. Opuntia vulgaris, Prickly Pear, or Indian Fig, with its succulent jointed stem and stellate spines.

... 484. Disgram of the flower of Opuntia, showing numerous sepals and petals, which pass insensibly into each other, indefinite stamens (often 300 or 400), and a one-ciled overy formed of several carpels, with parietal piscentas.

483 and 484).—Succulent often spiny herbs, with remarkable stems, which are angular, two-edged, or leafy, and have their woody matter often arranged in a wedge-like manner. Calyx of numerous sepals combined and epigynous. Petals indefinite. Stamens co, with long filaments.

stigmas several. Fruit baccate. Seeds exalbuminous. Natives of America. The fruit of many of the Indian Figs is subacid and refreshing. In some instances, it is sweetish and insipid. The stems of some of the species are eaten by cattle. The plants of the Cactus tribe present remarkable stems; sometimes spherical (Fig. 142), sometimes articulated or jointed (Fig. 483), and sometimes assuming the form of a tall upright polygonal column. Cercus grandiflorus is a night-flowering plant, so is also C. nycti-calus and some other species. Opuntia cochinellifera, the Nopal plant, affords nourishment to the Coccus Cacti or Cochineal insect in Mexico and Peru.

Nat. Ord. 105.—Grossulariaceæ, the Gooseberry order.—Shrubs which are either spiny or prickly or unarmed, with alternate palmately-lobed leaves without true stipules. Calyx-tube adherent to the ovary, limb 4-5lobed, sometimes coloured. Petals small, 5. Stamens 5. Ovary 1-celled, with 2 parietal placentas; styles more or less united. Fruit a berry, crowned with the remains of the flower, with two parietal placentas (Fig. 323). Seeds numerous, albuminous; embryo minute. Natives of the temperate regions of Europe, Asia, and America. Wholesome plants, furnishing often edible fruits, containing malic and other organic acids. *Ribes Grossularia*, the Gooseberry; *R. nigrum*, the Black Currant; *R. rubrum*, the Red Currant, furnish valuable fruits.

Nat. Ord. 106.—ESCALLONIACEÆ, the Escallonia order -Evergreen shrubs, often odoriferous, with alternate exstipulate leaves, allied to the last order, and differing from it in their capsular bicarpellary fruit, epigynous disk, axile placentas, and oily albumen. By some they are placed among Saxifrages, from which they differ in their simple style and oily albumen. Natives chiefly of South America. Escallonias attain a high elevation on the mountains.

Nat. Ord. 107.—Saxifragaceæ, the Saxifrage order (Fig. 485).—Herbs with alternate leaves. Calyx of 4-5

more or less cohering sepals. Petals 5 or 0. Stamens 5-10. Ovary more or less completely inferior, consisting of 2 carpels which diverge at the apex. Fruit a 1 or 2-celled capsule. Seeds numerous; embryo straight in fleshy albumen. Natives of northern alpine districts. Their properties are astringent. Heuchera americana is called alum-root on ac-count of its astringency.

Nat. Ord. 108.—Hydranace.

Diagram of the flower of Saxi-fraga tridactylites, with 5 di-visions of the calyx, 5 petals, 10 stamens in 2 rows, and a

Nat. Ord. 108.—HYDRANGE-ACEÆ, the Hydrangea order.-

Fig. 485.

bicarpellary pistil with nu-merous ovules.

Shrubs with simple exstipulate leaves, often considered as a sub-order of Saxifragaceæ, but differing in their opposite leaves, their tendency to form abortive radiant flowers, and in the carpels being often more than two. Natives of the temperate regions of Asia and America. Hydrangeas from China and Japan are commonly cultivated. Some of the species are used instead of Tea.

Nat. Ord. 109.—CUNONIACEÆ, the Cunonia order.— Trees or shrubs allied to Saxifragaceæ, and differing in their shrubby growth, opposite leaves, and interpetiolar stipules. The latter character separates them from Hydrangeas, which are exstipulate. Natives of the Cape of Good Hope, South America, the East Indies, and Australia. Their properties are astringent.

Nat. Ord. 110.—BRUNIACEÆ, the Brunia order.—Heathlike shrubs, with small, rigid, entire leaves. Calyx usually superior, 5-cleft. Petals and stamens 5; anthers extrorse. Ovary 1-3-celled, with 1-2 suspended ovules in each cell; style simple or bifid. Fruit either dehiscent and 2-celled, or indehiscent and 1-celled. Seeds solitary or in pairs; Botany. embryo minute, in fleshy albumen. Natives chiefly of the feræ, from which they differ in having the ovary composed Botany.

Cape of Good Hope.

Nat. Ord. 111.—HAMAMELIDACEÆ, the Witch-Hazel order.—Trees or shrubs, with alternate, feather-veined leaves, having deciduous stipules. Calyx 4-5-divided. Petals 4, 5, or 0. Stamens 8; anthers introrse. Ovary 2-celled, inferior; ovules solitary or several; styles 2. Fruit a 2-valved loculicidal capsule. Seeds pendulous, albuminous. Natives of North America, Asia, and Africa. Rhodoleia Championi is a showy plant, with red involucral leaves, found in China. Hamamelis virginica furnishes edible oily seeds.

Nat. Ord. 112.—Umbelliferæ or Apiaceæ, the Umbelliferous order,* (Figs. 486, 487).—Herbs with solid or

*Plates CXIX., CXX., and CXXI.

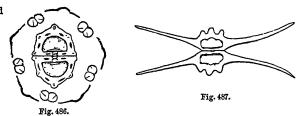

Fig. 486. Diagram of the flower of Fœniculum vulgare, common Fennel. The calyx limb is obsolete; there are 5 petals, 5 alternating stamens, and a cremocarp consisting of two achenes or mericarps united by their faces, with 5 primary ridges or jug4, and valleouize between them. There are 4 vittes on each side marked by dots between the ridges, and 2 on each side of the commissure. The albumen is solid, not furrowed or involute at the suture.

487. Transverse section of cremocarp or fruit of Angelica, showing the hemicarps or achenes forming it. There are 5 ridges on each achene, and the two lateral ones expand into long wings. The albumen is solid.

hollow stems, alternate leaves generally compound and sheathing at the base, and umbellate involucrate flowers (Fig. 163). Calyx adherent to the bicarpellary ovary, limb 5-toothed or obsolete. Petals 5, inflexed at the point (Fig. 319), often unequal, the outer ones being radiant. Stamens 5, alternate with the petals, and inserted with them on the outside of an epigynous disk or stylopod (Fig. 319). Styles 2. Fruit a cremocarp (diachænium), the 2 carpels or mericarps separating when ripe by their inner faces or commissure, and being suspended by a forked carpophore (Fig. 320); the carpels marked with ribs or ridges called juga and intervening spaces called valleculæ, and often containing vittæ. Seed solitary, pendulous; embryo mi ute, in the base of horny albumen. The Sections formed from the nature of the albumen, whether flat or curved, are not now adopted, inasmuch as they are found to be unsatisfactory. In the genera, the ridges on the fruit, the presence or absence of vittæ, and the form of the albumen, are taken into account. The umbels are sometimes reduced to a sort of head by the absence of peduncles. Natives of the northern parts of the northern hemisphere, and found high on the mountains of the tropics.

The properties of Umbelliferous plants are various. Some are harmless and esculent, such as the Carrot, Parsnip, Skirret and Parsley; others are acro-narcotic poisons, as Hemlock; a third set are antispasmodic, owing to the presence of a gum-resin containing a fetid sulphur oil, such as Assafœtida; while a fourth set are carminative from containing a volatile oil, as Caraway (Carum Carui), and Coriander (Coriandrum sativum). Conium maculatum, Hem-PI. CXX. lock,* used medicinally as an anodyne, contains a very active volatile oleaginous alkali called Conia, which causes death by paralysing the muscles of respiration. Dorema Ammoniacum, or Diserneston gummiferum, a Persian plant, yields gum Ammoniac. Narthex Assafætida, a plant found in Persia and Affghanistan, furnishes the true Assafætida. Opoponax Chironum, or Pastinaca Opoponax, produces the gum-resin called Opoponax.

Nat. Ord. 113.—Araliaceæ, or Hederaceæ, the Ivy order.—Trees, shrubs, or herbs with the habit of Umbelli-

of more than 2 carpels which do not separate in fruit, but become drupaceous or baccate, and in having fleshy in place of horny albumen. They are found in tropical and sub-tropical regions. The properties of the order are aromatic, stimulant, and tonic. Aralia papyrifera, Bokshung of China, found in the island of Formosa, is the plant which supplies the Chinese Rice paper. The black berries of *Hedera Helix*, common Ivy, are emetic and purgative. Panax Schinseng is the Asiatic Ginseng root, extravagantly prized by the Chinese as a stimulant and restorative.

Nat. Ord. 114.—Cornaceze, the Cornel order.—Chiefly trees or shrubs, with leaves almost always opposite and exstipulate; flowers in cymes or in involucrate heads. Calyx adherent, limb 4-toothed. Petals 4, valvate in æstivation. Stamens 4, alternate with the petals. Styles united into one. Ovary 2-celled; ovules solitary, pendulous. Fruit a 2-celled drupe. Embryo in fleshy albumen. Natives of the temperate regions of Europe, Asia, and America. The plants of this order have tonic and febrifugal properties. Some are astringent. The bark of various species of Cornus, as C. florida, C. sericea, and C. circinata, are used as substitutes for Cinchona in the United States.

2. Monopetalæ or Gamopetalæ.

Nat. Ord. 115 .- LORANTHACEE, the Mistleto order (Fig. 488).—Parasitic shrubs with articulated branches, opposite

exstipulate fleshy leaves, and hermaphrodite or unisexual flowers. Calvx tube adherent to the ovary, bracteated. Corolla of 4-8 united petals. Stamens 4-8, opposite the petals. Ovary 1-celled; ovule solitary, pendulous. Fruit inferior, succulent. Albumen fleshy. In place of one order, Miers makes two, Loranthaceæ and Viscaceæ. Loranthus, which is the type of the first, has showy dichlamydeous hermaphrodite flowers, lengthened stamens, and an ovary containing a solitary suspended ovule; while Viscum (Fig. 488), the type of the second, has small, monochlamydeous, diœcious flowers, with nearly

Fig. 488. Viscum album, the Mistleto, a parasitic plant, illustrating the natural order Loranthaceæ. By some it is placed in a Monochlamy-deons order called Visca-

sessile stamens, and an ovary containing 3 ovules attached to a free central placenta, one of the ovules only being perfected in the baccate fruit. The order Viscaceæ is placed near Santalaceæ. Natives chiefly of the equinoctial regions of Asia and America; a few are European and African. Astringent properties prevail in the order. The plants are truly parasitic, and they have often a peculiar woody structure with scalariform vessels. Occasionally 2 or 3 embryos are produced in the seed.

Nat. Ord. 116.—CAPRIFOLIACEE, the Honeysuckle order.-Shrubs or herbs, often twining, with opposite, exstipulate leaves (Fig. 137). Calyx adherent to the ovary, limb 4-5-cleft, usually bracteated. Corolla regular or irregular. Stamens 4-5, alternate with the corolline lobes. Ovary 3-5-celled; stigmas 3-5. Fruit usually a berry, one-celled, crowned by the calyx-lobes. Albumen fleshy. Natives chiefly of the northern parts of Europe, Asia, and America. Some of the plants are astringent, others have emetic and purgative properties. Many have showy and fragrant flowers. Lonicera Periclymenum, common Honeysuckle or Woodbine, possesses emetic and purgative qualities. The flowers of Sambucus nigra, common Elder, yield a volatile oil, and the berries are used in making a kind of wine.

Nat. Ord. 117.—CINCHONACEE, the Cinchona order

Botany.

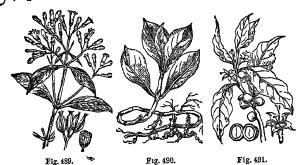

Fig. 489. Cinchona, the genus whence the order is named. It embraces the species of Peruvian or Jesuit's Bark. The plants have opposite leaves and interpetiolar stipules, with a 2-celled seed-vessel, and flowers in corymbose cymes.

490. Cephaelis Ipecacuanha, with its annulated root.

491. Coffea at abota, the Coffee tree, a native of Arabia and the confines of Abyssinia. It has a succulent reddish-brown fruit and horny albumen, which, when roasted, supplies the beverage called Coffee.

opposite leaves, interpetiolar glandular stipules and cymose inflorescence. Calyx adherent, entire, or toothed. Corolla regular. Stamens attached to the corolla. Ovary 2-celled; style 1. Fruit inferior, separating into 2 cocci, or indehiscent and dry, or succulent. Seeds definite and erect or ascending, or indefinite and attached to a central placenta; embryo small, in horny albumen. Chiefly found in tropical regions. This extensive order furnishes many important products. The plants have tonic, stimulant, febrifugal, emetic, and purgative properties. Some species are said to have intoxicating and even poisonous qualities. Many of the plants of the order have flowers remarkable for their beauty and odour. Cephaelis Ipecacuanha (Fig. 490) has an annulated root which is the Ipecacuan of the Pharmacopœias. It is emetic and diaphoretic, and contains a principle called Emetine. Cinchona (Fig. 489), is the genus which furnishes the species of Peruvian-bark trees. They contain three important alkalies, Quinine, Quinidine, and Cinchonine, combined with Kinic acid, and a peculiar variety of tannin. Coffee arabica (Fig. 491), the Coffee tree, has a succulent fruit of a reddish-brown colour when ripe. The hard albumen is used to furnish the well-known beverage. It contains a bitter principle called Caffeine, which is identical with Theine. An astringent extract called Gambeer is prepared by the Malays from the leaves of Uncaria Gambir.

Nat. Ord. 118.—Galiaceæ or Stellatæ, the Madder

order (Fig. 492).—Herbs agreeing in most points with Cinchonaceæ, and often included with them in a common order called Rubiaceæ. The chief distinguishing marks are their square stems, verticillate and exstipulate leaves. The name Stellatæ is derived from the star-like arrangement of the leaves. Some look upon the verticils as made up partly of true leaves, and partly of stipules. Natives of the northern parts of the northern hemisphere and of high mountains in South America and

Fig. 492. Diagram of the flower of Madder with the rim-like calycine limb, 5 parts of the corolla, 5 stamens, and a 2-celled and 2-seeded overy.

Australia. The plants supply important dyes. Some have tonic and diuretic properties. The horny albumen of Galium Aparine has been used for Coffee. Rubia tinctorum, Madder root, is a most important dye-stuff used in giving the colour called Turkey-red. The roots of R. cordifolia (Munjista) furnish the dye called Munjeet in India.

Nat. Ord. 119.—VALERIANACEE, the Valerian order,* (Figs. 493 to 495).—Herbs with opposite exstipulate leaves and cymose inflorescence. Calyx superior (Fig. 494), limb obsolete or forming a kind of pappus (Fig. 495). Corolla tubular, 3-6-lobed, sometimes gibbous, or spurred at the base (Fig. 494). Stamens 1-5, inserted on the corolla. Ovary

(Figs. 489 to 491).—Trees, shrubs, or herbs, with simple with one cell and 2 abortive ones; ovule solitary. Fruit Botany. dry and indehiscent, with 1 fertile cell, sometimes pappose (Fig. 495). Seed suspended, exalbuminous. Natives of temperate climates in Europe, Asia, and America. Many

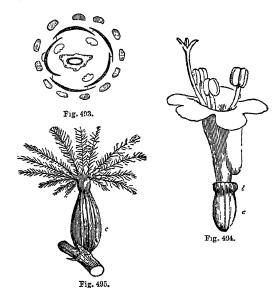

Fig. 493. Diagram of Valerian, showing calycine feathery pappus, 5 lobes of the corolla, one gibbous, 3 stamens, and one perfect ovarian cell with a single ovule.

494. Flower of Valerian, with adherent calycine tube, I, obsolete limb, c, which becomes pappose, irregular corolla gibbous at the base and with a 5-lobed limb, 3 stamens, and one style with 3 stigmas.

495. Fruit, c, of Centranthus ruber, Ited Valerian, indehiscent, containing one perfect seed (2 others being abortive), and having a feathery pappose calyx-limb at the apex, I.

of the plants in the order are strong-scented or aromatic, owing to the presence of a peculiar volatile oil. In medicine, they are employed as tonics and antispasmodics. The leaves of Centranthus ruber, Red Valerian, are used as a salad. Nardostachys Jatamansi appears to be the plant which supplied the ancient Spikenard. Valeriana officinalis* furnishes the Valerian root of the druggists. which *Plate yields Valerianic acid, and is used as an antispasmodic in CXXII.

nervous affections.

Nat. Ord. 120.—DIPSACACEE, the Teazel order.—Herbs or undershrubs, with opposite or whorled, exstipulate leaves, and flowers in capitula surrounded by an involucre. Calyx adherent, membranous, surrounded by an involucel. Corolla tubular, with an oblique 4-5-lobed limb. Stamens 4, anthers distinct. Ovary 1-celled; ovule pendulous. Fruit dry, indehiscent, crowned by the pappus-like calyx. Seed albuminous. Natives of the south of Europe, the Mediterranean, and the Cape of Good Hope. Some of the species are used in dressing cloth. Astringent qualities reside in some of the plants. The dried heads of Dipsacus Fullonum, Fuller's Teazel, with their uncinate spiny bracts, are used by fullers.

Nat. Ord. 121.—CALYCERACEÆ, the Calycera order.— A small order of herbs with alternate exstipulate leaves, and capitate flowers, intermediate between Dipsacaceæ and Compositæ, differing from the former in their united filaments and partially united anthers, and from the latter in their pendulous ovule, albuminous seed, and in their anthers. They inhabit the cooler parts of South America.

Nat. Ord. 122.—Compositze or Asteraceze, the Composite order (Figs. 496 to 499).—Herbs or shrubs with alternate or opposite, exstipulate leaves, and hermaphrodite or unisexual flowers (called florets) collected into dense capitula on a common receptacle (Figs. 496 and 174), and surrounded by a set of bracts (called phyllaries), forming an involucre (Fig. 151), the separate florets being often furnished with bractlets in the form of chaff (called squamæ or paleæ). Calyx adherent, limb entire or toothed, or mostly

*Plate CXXIL Botany. expanded into a pappus (Fig. 228). Corolla regular or irregular (Figs. 497 and 498). Stamens 5; anthers syn-

genesious (Fig. 252). Ovary single; style 1, bifid at the apex when fertile (Fig. 498); stigmas on the inner surface of each branch of the style (Fig. 499). Fruit an achene,

Fig. 497. Fig. 498. Fig. 499.

Fig. 497. Tubular gamopetalous corolls of Milfoil (Achillæa) with an inferior ovary, and an obsolete calyoine limb.

... 498. Ligulate flower of Milfoil (Achillæa), with the forked style projecting beyond the tube. There is no pappus. The flower is pistilliferous (femals)

(female).

(female).

499. Style of Achillæa Millefolium, Milfoil, forking so as to form 2 papillose stigmatic surfaces, which are curved outwards.

crowned with the limb of the calyx (Fig. 155). Seed solitary, erect, exalbuminous; embryo straight. The plants are found in all parts of the world. In warm countries they sometimes assume arborescent forms. There are between 9000 and 10,000 known species.

The plants of this very extensive order have been variously divided by authors. They were included by Linnæus in his class Syngenesia, the divisions of which have been already given. By Jussieu the following divisions have been established:-1. Cichoraceæ, the florets all ligulate and perfect. Ex. Cichorium. 2. Cynarocephalæ, the florets all tubular, homogamous, or those of the ray neuter; style swollen below its branches. Ex. Carduus. 3. Corymbiferæ, florets of the same head all homogamous (usually tubular); or those of the circumference filiform or tubular and pistilliferous, or ligulate; style of the perfect florets not swollen below its branches. Ex. Anthemis. De Candolle gives the following primary divisions:-1. Tubulifloræ (embracing Cynarocephalæ and Corymbiferæ of Jussieu), hermaphrodite flowers, tubular, with 5, rarely 4, equal teeth. 2. Labiatifloræ, hermaphrodite flowers, or at least the unisexual ones, two-lipped. This includes chiefly some peculiar American genera. 3. Ligulifloræ (Cichoraceæ of Jussieu), all the florets hermaphrodite and ligulate. Under these suborders De Candolle formed tribes from the form and nature of the style and stigma, attention being paid to the mode in which the branches of the style separate, the nature and extent of the papillæ, and the hairs on the stigmatic surface and on the style, &c.

The properties of Composite plants are various. Bitterness seems to prevail in the order to a greater or less degree. This is accompanied with tonic, stimulant, aromatic, or even narcotic qualities. Cichorium Intybus Chicory, or Wild Succory (Fig. 375), is much cultivated,

especially in France and Germany. Its roots are used as a substitute for Coffee, or as an addition to it. C. Endivia is the Endive or garden Succory, the leaves of which are used as a salad when etiolated. Lactuca virosa,* Wild Lettuce, *Plate gives out abundantly a white juice which, when inspissated, CXXIII. constitutes the anodyne narcotic called Lactucarium, or Lettuce-opium. L. sativa, common Lettuce, also yields a similar juice. Leontodon Taraxacum,* common Dandelion, has *Plate a milky juice which, when concrete, has been used medi-CXXIV. cinally as a diuretic, and economically as Coffee. The dried flowers of Carthamus tinctorius, Safflower, yield a pink dye. Cynara Scolymus, or the common Artichoke, has a succulent receptacle, which is used for food. Anacyclus Pyrethrum, Pellitory of Spain, is used medicinally to promote the flow of saliva. The flowers of Anthemis nobilis, Chamomile, act as an emetic and diaphoretic; the extract is bitter tonic. Arnica montana, Leopard's-bane, or Mountain Tobacco, has been given in nervous diseases as an acrid stimulant. Artemisia Absinthium, and other species of Wormwood, are bitter stomachic, and anthelmintic.

Nat. Ord. 123.—Brunoniaceæ, the Brunonia order.— Herbs with radical exstipulate leaves, and capitulate, involucrate flowers supported on scapes. Calvx free, in 5 divisions. Corolla 5-parted, inserted at the base of the calyx. Stamens inserted with the corolla. Ovary 1-celled; ovule solitary; stigma inclosed in a 2-valved cup. Fruit a utricle, inclosed in the hardened calycine tube. Seed erect, exalbuminous. Australian plants.

Nat. Ord. 124.—GOODENIACEÆ, the Goodenia order.— Herbs, rarely shrubs, not lactescent, with scattered exstipulate leaves, and distinct, not capitate flowers. Calyx usually superior, 3-5-divided. Corolla more or less superior, usually irregular, with a split tube and a 5-parted lipped limb; æstivation conduplicate. Stamens 5, separate. Ovary 1-2celled; placenta free, central; stigma surrounded by an indusium. Fruit capsular or drupaceous. Seeds albuminous. Natives chiefly of Australia, and the islands of the southern ocean. Some of the plants are used as esculent vegetables, and their pith is employed for economical purposes. Scavola Taccada furnishes Rice-paper in the Malay Archipelago.

Nat. Ord. 125.—STYLIDIACEÆ, the Stylewort order (Fig. 380).—Herbs or undershrubs, with scattered or whorled exstipulate leaves. Calyx adherent, with 2-6 divisions. Corolla usually irregular, 5-6-divided; æstivation imbricate. Stamens 2; filaments united with the style into a column; anther-lobes on the top of the column lying over the stigma. Ovary usually 2-celled, often with 1 or 2 epigynous glands in front. Fruit usually a 2-celled and 2-valved capsule. Seeds albuminous. Peculiar plants, remarkable for their gynandrous structure and for their irritable column. Natives chiefly of the swamps of Australia.

Nat. Ord. 126.—Campanulaceæ, the Hare-bell order

Fig. 501.

Fig. 500. Diagram of the flower of Campanula Rapunculus, Rampion, showing 5 divisions of the calycine limb, 5 reduplicately-valvate divisions of the corolla, 5 stamens, alternating with the corolline lobes, and a 3-celled ovary.

... 501. Vertical section of the flower of Campanula Medium; superior calyx, ovary with central placenta and numerous seeds, stamens with filaments dilated at the base, and anthers applied to the collecting hairs on the style.

(Figs. 500 and 501).—Lactescent herbs or undershrubs,

with alternate exstipulate leaves, and usually showy blue or white flowers. Calyx superior, limb commonly 5-cleft, persistent (Fig. 501). Corolla regular, campanulate, usually 5-lobed, marcescent (Fig. 501 and Fig. 219). Stamens 5, distinct. Style with collecting hairs (Fig. 384). Fruit a 2 or many-celled capsule, loculicidal, dehiscing by openings at the sides or by valves at the apex. Seeds numerous, albuminous, attached to a central placenta. Chiefly natives of the northern parts of Europe, Asia, and North America. Those with capsules opening by lateral pores appear to be natives of the northern hemisphere; those with apicilar valves, of the southern. The Belloworts have an acrid milky juice, but occasionally the young shoots and roots are cultivated as articles of food. Campanula Rapunculus, Rampion, is used as an esculent vegetable.

Nat. Ord. 127.—LOBELIACEÆ, the Lobelia order.—Lactescent herbs or shrubs, with alternate, exstipulate leaves. Calyx superior, limb often 5-lobed. Corolla irregularly 5-lobed, often deeply cleft. Stamens 5, epigynous, synantherous. Stigma fringed. Fruit capsular, 1 or more celled, dehiscing at the apex. Seeds numerous, albuminous. Natives chiefly of tropical or sub-tropical climates. The Lobeliads have usually an acro-narcotic milky juice, and hence the species are often poisonous. The milky juice is sometimes used for caoutchouc. Lobelia inflata, a North American species, is used medicinally under the name of Indian Tobacco, as an antispasmodic and sedative, as well as an

Nat. Ord. 128.—Styracaceæ or Symplocaceæ, the Storax order.—Trees or shrubs, with alternate, exstipulate leaves, usually with stellate tomentum. Calyx free, persistent, with 5 or 4 lobes, or entire. Corolla 5 or 10-divided. Stamens definite or indefinite, arising from the corolla, more or less cohering. Ovary 3-5-celled. Ovules partly erect and partly pendulous. Fruit succulent, inclosed by the calyx, often unilocular by abortion. Seeds albuminous. Miers divides this into two orders, Styracaceæ and Symplocaceæ, the former distinguished by their uniserial stamens, linear anthers, superior ovary, free central placenta, one-seeded drupe, and stellate hairs. Sparingly distributed, chiefly in tropical and subtropical regions. Some of the plants are bitter and aromatic, others yield a fragrant stimulant resin. Styrax Benzoin, a tree of the Malay Archipelago, produces the concrete balsamic exudation Benzoin, which is employed medicinally as an expectorant, and is also used for incense. S. officinale, a native of Syria, produces the resin called Storax, which is prescribed as a pectoral

Nat. Ord. 129.—COLUMELLIACEÆ, the Columellia order. -Evergreen shrubs or trees, with opposite exstipulate leaves and yellow flowers. Calyx adherent, 5-parted. Corolla rotate, 5-8-parted Stamens 2, on the corolla. Anthers sinuous. Disk epigynous. Fruit a 2-celled polyspermal capsule. Seeds albuminous. A small and doubtful order, placed by Lindley in his Cinchonal Alliance. Natives of Mexico and Peru.

Nat. Ord. 130.—VACCINIACEÆ, the Cranberry order.-Shrubs with alternate exstipulate leaves. Calyx superior. Corolla 4-6-lobed. Anthers biporose, with appendages. Fruit succulent, 4-10-celled. Seeds albuminous. The order differs from Ericaceæ chiefly in its epigynous calyx. Natives of temperate regions, and found often in sub-alpine swamps. Astringent properties prevail in the order. The berried fruit is subacid and eatable. Oxycoccus palustris (Vaccinium Oxycoccus), a marsh plant, produces the Cranberry in Britain. O. macrocarpa is the American Cranberry. Vaccinium Myrtillus is the Bilberry or Blaeberry.

Note.—In some Calycifloral Exogens the insertion of the stamens is so near the base of the calyx, that it is difficult to separate them from Thalamifloral Exogens. This may be seen in Legu-minosæ and Portulacaceæ. Occasionally the petals are abor-

tive, so that the plants become monochlamydeous. The orders Botany. in which this anomaly occurs are :- Celastraceæ, Rhamnaceæ, Amyridaces, Leguminoss, Rosaces, Lythraces, Combretaces, Myrtaces, Halorageaces, Passifloraces, Portulacaces, Illecebracez, Tetragoniacez, Saxifragacez, Cunoniacez, and Loranthaceæ.

SUB-CLASS III .- COROLLIFLORÆ. 1. Hypostamineæ.

Nat. Ord. 131.—ERICACEÆ, the Heath order* (Figs. 502, *Plate 503).—Shrubs or undershrubs with evergreen, rigid, entire, OXVIII. whorled or opposite, exstipulate leaves (Fig. 503). Calyx figs. 6-11

Fig. 502. Diagram of Erica, showing a tetramerous flower, having 4 divisions of the calyx and corolla, 8 stamens, and a 4-valved capsule.

508. Erica cinerca, fine-leaved Heath, showing its entire exstipulate leaves and ovate ventricese corolla with a 4-divided limb.

Fig. 503.

inferior, 4-5-cleft, persistent. Corolla 4-5-cleft. Stamons 8-10 or twice these numbers, hypogynous. Anthers 2celled, biporose, with appendages. Ovary surrounded by a disk or scales. Fruit capsular, rarely baccate. Seeds numerous, with an adherent testa, and cylindrical embryo in the axis of fleshy albumen. They abound at the Cape of Good Hope, and occur also in Europe, America, and Asia. Some of the Heathworts are astringent, others have edible fruit, and others, such as species of Rhododendron, Kalmia, and Ledum, are poisonous. The species of Erica have no active properties. Arbutus Unedo bears a fleshy fruit like a Strawberry, and hence it is called the Straw-Arctostaphylos Uva-Ursi, Bearberry, is an berry tree. astringent. An infusion of its leaves is prescribed in discharges from the mucous membrane of the bladder.

Nat. Ord. 132.—Pyrolaceze, the Pyrola, or Wintergreen order.—Herbs, with simple leaves, generally included as a sub-order of Ericaceæ, but distinguished by their habit, their more or less declinate styles, loose testa, and minute embryo at the base of fleshy albumen. Natives of northern countries. Chimaphila umbellata is tonic and diuretic.

Nat. Ord. 133.—MONOTROPACEÆ, the Monotropa, or Fir-Rape order.—Parasitic plants of a brown colour, allied to Pyrolaceæ, but differing in their scaly stems, in the longitudinal dehiscence of their anthers, and in their minute embryo being at the apex of the albumen. They are also considered by many as a sub-order of Ericaceæ, from which their habit, their antherine dehiscence, loose testa, and minute embryo, separate them. Chiefly found parasitic on Firs in Europe, Asia, and North America.

Nat. Ord. 134.—EPACRIDACEÆ, the Epacris order.— Shrubby plants, with usually alternate, simple, and parallelveined leaves, having overlapping bases; flowers commonly pentamerous. They represent the Heaths in Australia, and differ from Ericaceæ principally in having one-celled anthers without appendages. Natives of the Indian Archipelago and Australia.

2. Epicorollæ or Epipetalæ.

Nat. Ord. 135.—EBENACEÆ, the Ebony order.—Trees

Botany. or shrubs not lactescent, with alternate, exstipulate, coriaceous, entire leaves, and polygamous flowers. Calyx 3-7cleft, persistent. Corolla 3-7-cleft, often pubescent. Stamens usually twice or quadruple the number of the corolline segments; anthers with longitudinal dehiscence. Ovary 3 or several-celled; style with as many divisions; ovules 1 or 2 in each cell, pendulous. Fruit a round or oval berry; seeds large and bony, albuminous. Chiefly tropical plants. Many are found in India, a few in colder climates. The trees of this order are remarkable for their hard and valuable timber. The bark of some of the species is astringent, while the fruit is in many cases eatable. The heartwood of several species of Diospyros constitutes different kinds of Ebony.

Nat. Ord. 136.—AQUIFOLIACEÆ or ILICACEÆ, the Holly order.—Evergreen trees or shrubs, with coriaceous, exstipulate leaves, and small axillary flowers. Calyx of 4-6 sepals. Corolla 4-6-parted. Stamens 4-6, alternate with the corolline segments; anthers dehiscing longitudinally. Ovary 2-6-celled; a single pendulous ovule in each cell. Fruit fleshy, containing from 2 to 6 nucules. Embryo minute in fleshy albumen. Natives of various parts of the world, but sparingly distributed. Bitter, tonic, astringent, and emetic properties exist in the order. Some are used as tea. Ilex Aquifolium, the common Holly, has a tonic bark, which has been used in intermittents. I. paraguayensis is called Maté in South America, where its leaves are used for tea; they contain Theine.

Nat. Ord. 137.—Sapotace &, the Sapodilla order.—Trees or shrubs, often with milky juice, alternate, coriaceous, entire, exstipulate leaves, and hermaphrodite flowers. Calyx Corolla 4-8-cleft, sometimes with numerous 4-8-parted. segments. Stamens definite, half of them petaloid and sterile; anthers extrorse. Ovary 4-12-celled, with a single pendulous ovule in each cell; style 1. Fruit baccate. Seeds with a bony testa, usually albuminous. Natives of the tropics chiefly. The fruit of many of the plants of this order is edible. The bark is bitter and febrifugal. Some furnish caoutchouc, and others fatty matter. Achras Sapota produces the edible Sapodilla Plum. Bassia butyracea has an oily fruit which furnishes a kind of butter used in Nepal. The Shea, or Galam butter of Mungo Park, is the product of another species. Isonandra Gutta is the Taban-tree, which furnishes Gutta Percha.

Nat. Ord. 138.—MYRSINACEÆ, the Myrsine order.—Trees or shrubs, with coriaceous, exstipulate, smooth leaves, and flowers often marked with glandular dots or lines. Calyx and corolla 4-5-cleft. Stamens 4-5, opposite the corolline segments, occasionally 5 alternate sterile ones. Ovary unilocular, with a free central placenta in which the ovules are imbedded. Fruit fleshy. Seeds 1 or more, with horny albumen. The plants are said to resemble Primulaceæ in everything except their arborescent habit, fleshy fruit, and pitted placenta. They are limited in their geographical range, and abound in islands with an equable temperature, as the islands of the Indian Ocean, Mauritius, Bourbon, and Madagascar. Many of them are handsome evergreen shrubs. The seeds of Theophrasta Jussiai supply flour for bread in St Domingo, and the fruit of Myrsine africana is mixed with barley for the food of asses in Abyssinia.

Nat. Ord. 139.—Jasminaceæ, the Jasmine order.—Shrubs, often twining, with opposite or alternate, usually compound leaves. Calyx and corolla regular, with 5-8 divi-Stamens 2, included within the hypocrateriform corolla. Ovary 2-celled. Fruit a double berry or capsule. Seeds with little or no albumen and a straight embryo. Natives principally of tropical India. They are remarkable for their fragrance. The oil of Jasmine is obtained from Jusminum officinale and J. grandiflorum.

Nat. Ord. 140.—OLEACEÆ, the Olive order (Fig. 504).-

persistent, sometimes 0. Corolla 4-cleft, sometimes of 4 pe-Botany.

tals connected in pairs, sometimes 0. Stamens usually 2. Ovary 2-celled; ovules 2, pendulous in each cell. Fruit fleshy or dry, often 1seeded by abortion. Seeds albuminous; embryo straight. Natives of temperate climates. Some of the plants of the order have emollient and laxative properties; others are bitter, tonic, and febrifugal. Some supply oil, others manna. Fraxinus excelsior, the Ash, is distinguished by its samaroid fruit. Olea europæa (Fig. 504), the Olive, has a drupaceous fruit which yields, on expression, Olive Oil.

small seed which grows into a tree.

Fig. 504. Branch of Olea europæa, Olive, with drupes.

Nat. Ord. 141.—SALVADORACEÆ, the Salvadora order. -Small trees or shrubs, with opposite leaves and minute panicled flowers. Calyx of 4 minute sepals. Corolla 4partite. Stamens 4. Ovary superior. Fruit baccate, 1celled. Seed solitary, exalbuminous. The order is considered by Planchon as allied to Oleaceæ. Natives of Syria and India. The plants are acrid and stimulant, and some of them have properties like Mustard. Salvadora persica appears to be the Mustard-plant of Scripture. It has a

Nat. Ord. 142.—Asclepladaceæ, the Milkweed order. -Lactescent, often twining shrubs or herbs, having entire, usually opposite leaves, with interpetiolar stipulary cilia, Calyx 5-divided. Corolla 5-lobed, æstivation imbricate, rarely valvate. Stamens 5; filaments usually connate; pollen in wax-like masses (Fig. 382), cohering in pairs and attached to glands at the five angles of the stigma, which is common to the two styles. Fruit consisting of two follicles, containing numerous comose seeds (Fig. 329), with thin albumen. Chiefly tropical plants, found in Africa, India, and America. The Asclepiads have acrid, stimulating, purgative, diaphoretic, and emetic properties. Most of the species have milky juice containing caoutchouc. Asclepias tuberosa, the Butterfly-weed or Pleurisy-root, is employed medicinally in North America as a laxative and diaphoretic. Calotropis gigantea is the Mudar plant of Bengal. The bark is employed medicinally as an emetic and diaphoretic. Cynanchum monspeliacum has a purgative juice which is used at Montpellier to adulterate Scammony. Hemidesmus indicus is called Indian Sarsaparilla. because its roots are used in India as a substitute for that drug.

Nat. Ord. 143.—Apocynaceæ, the Dogbane order-(Fig. 505).—Trees or shrubs, usually milky, allied to the Asclepiadaceæ, and differing from them in the contorted æstivation of the corolla, distinct filaments, granular pollen, and a peculiar hourglass-like stigma (Fig. 506). Natives of the tropics of Asia, America, and Africa. Many of the plants are poisonous, some are drastic purgatives. The bark is sometimes tonic and febrifugal. The milky juice of several species supplies caoutchouc. Vinca, the Periwinkle, is the only British genus in the order. Apocynum cannabinum has emetic roots. Aspidosperma excelsum supplies the fluted Yarroura-wood used for paddles. Roupellia grata produces what is called Cream-fruit in Sierra Leone. Tabernæmontana utilis is the Cow-tree of Demerara. ghinia venenata yields the famous ordeal poison of Madagascar, called Tanghin.

Nat. Ord. 144.—LOGANIACEÆ or SPIGELIACEÆ, the Trees or shrubs with opposite, simple, or pinnate leaves. Calyx Strychnia order.—Shrubs, herbs, or trees, with opposite,

Botany. mens varying in number, not always isomerous with the corolla. Fruit a 2-celled capsule, with loose placentas, or a berry, or succulent, with 1 or 2 nucules. Seeds usually peltate, albuminous. Chiefly tropical. The plants of this

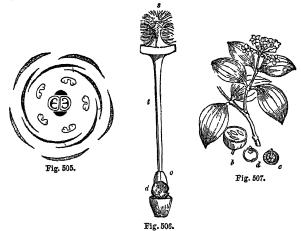

Fig. 505. Diagram of the flower of Vinca, Periwinkle, showing 5 divisions of the calyx, alternating with five of the twisted corolla, 5 stamens alternating with the corolline segments, and 2 carpels forming the nistil.

pistil.

508. Pistil of Vinca separated, showing the remarkable stigma, s, covered with hairs, and having an hour-glass contraction in the middle. Ovary, o, with disk, d, style, t.

507. Strychnos Nux-Vomica, the Poison-Nut, a tree abounding on the Malabar and Coromandel coasts. It has opposite ribbed leaves, a round fruit, b, of a reddish colour, about the size of a small orange. The seeds c, are circular, flat, and umblicated on one surface. They contain abundant albumen, d, and a small embryo.

order are highly poisonous. They produce tetanic convulsions and narcotism. Some of them are used medicinally as active remedies in certain kinds of palsy. Intense bitterness is met with in some of the species, and in very moderate doses they act as tonics. Ignatia amara, St Ignatius's Bean, produces convulsions and death. The peltate seeds of Strychnos Nux-Vomica (Fig. 507), produce powerful effects on the spinal marrow, and cause death by tetanus. They contain the alkaloid called Strychnia. The bark constitutes false Angustura.

Nat. Ord. 145.—GENTIANACEÆ, the Gentian order (Fig.

508, and Fig. 159).—Herbs, rarely shrubs, with opposite, entire, exstipulate, usually ribbed leaves, and showy variously-coloured flowers. Calyx divided, persistent. Corolla persistent, imbricate, induplicate, often twisted in æstivation, sometimes with a fringed limb. Stamens alternate with the coralline segments. Ovary of 2 carpels, placed to the right and left of the axis, one-celled, with 2 parietal, often intro-flexed, placentas; style 1; stigmas 2. Fruit a capsule or berry. Seeds

Fig. 508.

numerous, with fleshy albumen and a minute embryo. Natives of almost all parts of the world. Some are found at an elevation of 16,000 feet, others in hot tropical plains. Bitterness is the property which prevails generally in this order. Occasionally the species have emetic and narcotic qualities. Gentiana lutea, the yellow Gentian of the Alps, is a medicinal plant. Its root is used as a bitter tonic.

Nat. Ord. 146.—BIGNONACEÆ, the Trumpet-flower order.-Trees or twining or climbing shrubby plants, with ex stipulate usually opposite and compound leaves, and showy, often trumpet-shaped flowers. Their woody stem is sometimes divided in a cruciform manner. Calyx entire or di-

entire, stipulate leaves. Calyx inferior, 4-5-parted. Co- vided, often spathaceous. Corolla with a swollen throat, and Botany. rolla 4, 5 or 10-cleft; estivation convolute or valvate. Sta- a more or less irregular 4-5-lobed limb. Stamens 5, unequal, one generally abortive; sometimes didynamous. Ovary surrounded by a disk, 2-celled; carpels anterior and posterior; placentas in the axis. Fruit a 2-valved, often pod-like capsule, divided by a spurious placental dissepiment. Seeds winged, exalbuminous; embryo with broad leafy cotyledons. Natives of America. The bark of Jacaranda bahamensis, Palo de Buba, is used in the isthmus of Panama as an anthelmintic. Bignonia Chica supplies a red

> Nat. Ord. 147.—Gesneraceæ, the Gesnera orders (including Cyrtandraceæ).-Herbs or shrubs, often growing from scaly tubers, with rugose, usually opposite and whorled exstipulate leaves, and showy flowers. Calyx half-adherent, 5-parted. Corolla more or less irregular, 5-lobed. Stamens 2, or 4, didynamous, with the rudiment of a fifth; anthers often combined. Ovary 1-celled, surrounded by a disk in the form of glands or a ring. Fruit capsular or suc-culent, 1-celled, with 2 lobed parietal placentas to the right and left of the axis. Seeds numerous, albuminous. They are natives of various parts of the world, chiefly the warmer regions of America. The succulent fruits are occasionally eatable, and some of the species yield a dye.

> Nat. Ord. 148.—Crescentiaceæ, the Calabash-tree order.-Small trees, with exstipulate leaves, and flowers growing out of the old stems and branches. The plants are allied to Bignoniaceæ, from which they differ in their parietal placentas, their wingless seeds, fleshy cotyledons, and in the pulpy contents of their woody indehiscent fruit. Natives of tropical regions. Crescentia Cujete, the Calabash-tree, has a gourd-like fruit with a hard shell which is used for

> Nat. Ord. 149.—PEDALIACEÆ, the Pedalium order.— Glandular herbs, with exstipulate leaves and large bracteated flowers. They are allied also to Bignoniaceæ, from which they differ in their parietal placentation, their wingless seeds with a papery episperm. From Crescentiaceæ they are distinguished by the want of pulp in the fruit. The ovary, at first 1-celled, sometimes becomes divided by placental septa into 4 or 6 cells. Natives of tropical countries, especially Africa. The plants of the order have generally a heavy odour. Their seeds yield oil as well as starchy matter.

Nat. Ord. 150.—Polemoniaceæ, the Phlox order (Fig.

509).—Herbs, with opposite or alternate leaves. Calyx 5-cleft. Corolla regular, 5-lobed, convolute. Stamens 5, alternate with the corolline lobes; pollen blue. Ovary superior, 3-celled; style 1; stigma trifid. Capsule 3celled, 3-valved, valves separating from the axis. Seeds albuminous, often with a mucous covering containing spiral threads, which spread out in coils when water is applied. Natives chiefly of the temperate parts of America. Polemonium cæruleum is commonly cultivated under the name of Greek Valerian.

Diagram of the flower of Polemonium cæruleum, shown for five sixted to the callyx, five convolute lobes of the corolla, five alternating stamens, and a tricar pellary ovary.

Fig. 509.

Nat. Ord. 151.—Hydrophyllaceæ, the Hydrophyllum order.—Herbs or small trees, usually with alternate and lobed hispid leaves. Calyx 5-cleft, often with appendages, persistent. Corolla regular, somewhat bell-shaped. Stamens 5, alternating with the corolline lobes. Ovary superior, with 2 parietal placentas, which often line the ovary; styles 2. Fruit a 2-valved, 1-celled, or spuriously 2-celled capsule, filled with a large placenta. Seeds reticulated; embryo small in hard albumen. Natives chiefly of the temperate parts of America. Some species are tropical.

Nat. Ord. 152.—DIAPENSIACEÆ, the Diapensia order. Prostrate shrubby plants, with crowded heath-like exstipu-

Botany. late leaves and solitary terminal flowers. They are in many respects allied to Polemoniaceæ, from which they differ chiefly in their imbricated bracts, transversely 2-celled anthers, and peltate seeds. These characters with the 3-celled ovary also separate them from Hydrophyllaceæ. Natives of northern Europe and North America.

Nat. Ord. 153.—Convolvulaceæ, the Convolvulus order (Figs. 510 to 512).—Herbs or shrubs, usually twining

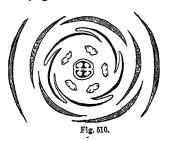

Fig. 511.

Fig. 510. Diagram of the flower of Calystegia (Convolvulus) sepium, Great
Bindweed, showing two bracts, five divisions of the calyx, five lobes
of the platted campanulate corolla, five stamens, and a two-celled
overly, with two ovules in each cell.

511. Convolvulus Scammonia, the Scammony plant, found in Greece and
the Levant. The concrete miky juice of the large root constitutes
Scammony, which is imported from Smyrns.

(Fig. 511), and lactescent, with alternate, exstipulate leaves

and regular flowers, having a unifloral or multifloral cymose inflorescence. Calyx 5divided, imbricated, persistent. Corolla plaited. Stamens 5, alternate with the corolline lobes. Ovary free, 2-4-celled; ovules 1-2 in each cell, erect; styles united, often divided at the apex. Capsule 2-4-celled, sometimes by absorption 1-celled, septifragal. Seeds large, with mucilaginous albumen; embryo curved (Fig. 512), with he curved embryo and planting of the curved embryo. 1-2 in each cell, erect; styles united, often crumpled cotyledons. Chiefly natives of the

tropics. The order is characterized by purgative properties, and it contains some important medicinal plants. Convolvulus Scammonia (Fig. 511), is the source of the purgative gum-resin, Scammony. Exogonium (Ipomæa) Purga is the plant which yields Jalap.

Nat. Ord. 154.—Cuscutaceæ, the Dodder order* (Fig. 426).—Leafless parasitic twining herbs, generally reckoned a sub-order of Convolvulaceæ. They are marked by scales alternating with the corolline lobes, and a filiform spiral acotyledonous embryo. The seeds germinate in the usual way, and afterwards the plants become true parasites. Some of them destroy Flax, Clover, and other crops. Natives of temperate regions.

Nat. Ord. 155.—CORDIACEE, the Sebesten order.—Trees with alternate, exstipulate, rough leaves. Calyx 4-5-toothed. Corolla 4-5-cleft, regular. Stamens alternate with the corolline segments; anthers versatile. Ovary superior, 4-8celled; stigma 4-8-cleft. Fruit drupaceous, 4-8-celled, with a single exalbuminous seed in each cell, pendulous by a long cord. Embryo with plaited cotyledons. The plants of this order are natives of the tropics. The drupes of Cordia Myxa and C. latifolia are called Sebesten plums, and are used as food. The bark is tonic.

Nat. Ord. 156.—Boraginaceæ, the Borage order (Figs. 513 and 514).—Herbs or shrubs with round stems, alternate, rough leaves, and flowers in scorpioidal cymes (Fig. 170). Calyx 4-5-divided, persistent. Corolla usually regular and 5-cleft (Fig. 513 and 225), imbricate, often with faucial scales (Fig. 236). Stamens alternate with the corolline segments. Ovary 4-lobed; style basilar (Fig. 514). Fruit 2 or 4 distinct achenes. Seed exalbuminous. The plants were called Asperifoliæ from their rough leaves. Natives of the northern temperate regions principally. Demulcent mucilaginous qualities pervade the order. Some of the

plants yield a dye, others are used as pot-herbs. Anchusa tinc- Botany.

toria, Alkanet, yields a reddish brown dye. Boragoofficinalis, Borage, when steeped in water, imparts coolness to it. Mertensia maritima, a sea-shore plant, has leaves which taste like oysters.

Nat. Ord. 157.—En-RETIACEÆ, the Ehretia

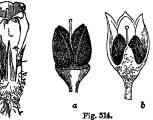

Fig. 513. RETIACEÆ, the Ehretia order.—The plants of this order are often reckoned a sub-division of the Borage order, from which they

differ in their terminal style, proceeding from a concrete 4-celled ovary, and their drupaceous fruit. Some of them, as the Peruvian Heliotrope, have a fragrant odour. They are generally tropical trees or shrubs.

Nat. Ord. 158.—Nolanaceæ, the Nolana order.—Herbaceous or shrubby plants with alternate exstipulate leaves, having characters in common both with Convolvulaceæ and Boraginaceæ. Their distinguishing characters are their straight inflorescence, valvate calyx, plaited corolla, ovary composed of 5 or more separate carpels, variously combined, united styles, somewhat capitate stigma, and embryo curved in a small quantity of albumen. South American plants.

Nat. Ord. 159.—Solanaceæ, the Potato order.*—Herbs *Plate or shrubs with alternate, often geminate leaves, cymose, CXXVI generally extra-axillary inflorescence, and isomerous flowers. Calyx and corolla, with 5, rarely 4, partitions. Corolline lobes nearly equal, æstivation valvate or induplicato-valvate. Stamens 5, very rarely 1 sterile; anthers opening by slits or pores (Fig. 260). Ovary generally bilocular; style simple; stigma 2-lobed or clavate. Fruit capsular or baccate (Fig. 207), with two cells, rarely more, from placental septa. Seeds albuminous; embryo curved (Curvembryeæ) or straight (Rectembryeæ). Natives of various parts of the world, and abundant within the tropics. The plants of this order do not display the marked narcotic properties of the next order, and their juice, according to Dr T. Anderson, does not cause dilatation of the pupil. Some of them yield edible tubers and fruit, others are tonic, pungent, and stimulant. The species of Capsicum yield Cayenne-pepper and Chillies, which are acrid and irritant. Lycopersicum esculentum produces the Tomato. Physalis peruviana yields an edible berried fruit called Peruvian Winter Cherry. Solanum tuberosum, the Potato, has starchy tubers. S. Dulca-

mara,* Bitter-sweet, or woody Nightshade, is used as a dia-*Plate phoretic in cutaneous diseases. S. Melongena and S. ovigerum, produce edible fruits known by the name of Egg-apples.

Nat. Ord. 160.-ATROPACEÆ, the Deadly Nightshade order* (Figs. 515 and 516).—This orit a separate order,

*Plate CXXVII. & CXXVIII.

Fig. 515. Fig. 516. der agrees in most Fig. 515. Diagram of the flower of Nicotiana Tabacum, Tobacco, showing five divisions of the cally a, five imbricate corolline lobes, five stamens, alternating with these lobes, and a dimerous ovary.

Botany.

longitudinally. The geographical distribution is similar to that of Solanaceæ. The plants of this order are in general narcotic poisons. Their juice has the property of causing dilatation of the pupil. Atropa Belladonna, Deadly Nightshade,* has shining brownish-black berries. It contains an alkaloid, Atropia, to which its narcotic properties are due. CXXVII. Datura Stramonium, Thorn-apple, is so called from its spiny capsule, which is spuriously four-celled. The leaves and seeds contain a narcotic alkaloid Daturia. Hyoscyamus niger, Henbane,* is a narcotic plant, the juice of which dilates the pupil. Its seed-vessel is a pyxidium. Mandra-CXXVIII. gora officinalis, the Mandrake, stimulates the nervous

system. Nicotiana Tabacum (Fig. 224) supplies American Tobacco. Nat. Ord. 161.—Orobanchaceæ, the Broom-rape order. -Leafless, scaly herbs, parasitic on the roots of other plants. Calyx 4-5-toothed, persistent. Corolla with an irregular or bilabiate limb, imbricate. Stamens 4, didynamous. Ovary 1-celled, with 2 or more parietal placentas; the 2 carpels forming the ovary placed to the right and left of the axis. Fruit a capsule, covered by the withered corolla, 1-celled, 2-valved. Seeds albuminous, minute. Natives of Europe, middle and northern Asia, North America, and the Cape of Good Hope. The properties of the order are bitter, astringent, and escharotic.

Nat. Ord. 162.—SCROPHULARIACEÆ, the Figwort order (Figs. 517 to 519).—Herbs or undershrubs, with opposite,

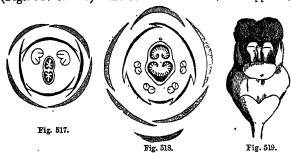

Fig. 517. Diagram of the unsymmetrical, slightly irregular, flower of Veronica, with four divisions of the calyx, four of the corolla, imbricate, two stamens, and a bilocular ovary.

518. Diagram of the flower of Antirrhinum majus, Frogsmouth, showing single bract below, five divisions of the irregular calyx, five segments of the irregular corolla, four perfect stamens, and a rudiment of a fifth above the ovary, a two-celled ovary composed of two carpels placed posteriorly and anteriorly as regards the axis.

519. Irregular lipped flower of Scrophularia, Figwort, with a transverse stammodium or abortive fifth stamen.

whorled, or alternate leaves, and anisomerous flowers. Calyx of 5 or 4 parts. Corolla irregular (Figs. 227, 229, and 230), lobes unequal, imbricate in æstivation. Stamens 2 (Fig. 230) or 4, didynamous, rarely 5, or with a rudimentary fifth (Fig. 519). Ovary bilocular, carpels anterior and posterior. Fruit capsular, rarely baccate, usually 2-celled. Seeds albuminous, with a straight or slightly curved embryo. Natives of all parts of the world, cold as well as hot. Some are root-parasites, as Eyebright, Cow-wheat, and Yellow-rattle. The Figworts are more or less suspicious in their properties. Some are acrid, others sedative. There are many showy garden plants in this order. Digitalis purpurea, Foxglove,* is used medicinally as a diuretic and sedative of the heart's action.

Nat. Ord. 163.—Labiatæ or Lamiaceæ, the Labiate or Dead-nettle order (Figs. 520 to 522).—Herbs or undershrubs, with tetragonal stems, opposite, exstipulate, often aromatic leaves, and flowers in verticillasters (Fig. 173). Calyx tubular, persistent, 5 or 10-toothed (Fig. 204), or bilabiate. Corolla bilabiate (Fig. 521). Stamens 4, didynamous (Fig. 253), or by abortion 2; anthers 2-celled, or 1celled by abortion (Fig. 245). Ovary deeply 4-lobed, on a disk, style basilar (Fig. 522); stigma bifid. Fruit 1-4 achenes, inclosed by the calyx. Seeds erect, with little or no albumen. Natives of temperate climates. Labiate plants have no de-

sometimes 1, very rarely 3, are sterile; anthers dehisce leterious qualities. They are generally aromatic and fragrant. Botany. Some are tonics. Many of them, such as Lavender, Mint,

... 521. Firegular bulabiate corolla of Lamium, showing upper and under lip and didynamous stamens.

... 522. Vertical section of flower of Salvia, showing two of the achenes, a, with the single style, st, the corolla, co, the calyx, c, and the discoid receptacle, r.

Thyme, Sage, Rosemary, Marjoram, Basil, Savoury, and Hyssop, are used as carminatives and antispasmodics, and are cultivated in gardens for culinary purposes. Many contain a kind of stearoptine like camphor. Oils are procured from the leaves of most of the species, and to these their fragrance is due.

Nat. Ord. 164.—VERBENACEÆ, the Vervain order (Fig. 523).—Herbs, shrubs, or trees, with exstipulate, usually op-

posite leaves, resembling much the Labiatæ in their characters, and differing in their achenes being concrete, their style terminal, and their leaves usually not containing receptacles of oil. Corolla generally irregular. Stamens 4, didynamous, or 2; anthers 2-celled. Seeds erect or ascending; radicle inferior. Natives both of tropical and of temperate regions. In the order are included the *Myoporaceæ*, which differ only in their seeds being pendulous and in the radicle of the embryo being superior. Bitter, tonic, as well as aromatic properties are found in the Vervains. Verbena ties are found in the Vervains. Verbena was supposed to have many valuable qua-

Nat. Ord. 165.—Selaginaceæ or Globulariaceæ, the Globularia order.—A small group of herbaceous or shrubby plants, with alternate exstipulate leaves and bracteated flowers resembling Verbenaceæ, from which they differ in their 1-celled anthers, pendulous ovules, and superior radicle. Globularia has a solitary carpel. Allied to this order and Vervains is a small group, Stilbaceae, of which the Cape genus Stilbe is the type; they have slightly irregular flowers, with 4 or 5 stamens, one often abortive, anthers 2-celled, ovary 2-celled, style terminal, fruit 1-seeded, seed erect, embryo inferior. Some of the species of Selaginaceæ are fragrant. They are natives of the Cape of Good Hope chiefly; some are European.

Nat. Ord. 166.—Acanthaceæ, the Acanthus order.— Herbs or shrubs, with simple, opposite, exstipulate leaves and bracteated showy flowers. Calyx of 5 sepals, distinct or combined, persistent. Corolla usually irregular, lipped. Stamens 4, didynamous, often 2 by abortion. Ovary of 2 carpels, placed anterior and posterior; placentas parietal, but extending to the axis; style 1. Fruit a 2-celled capsule, opening by elastic valves. Seeds 1, 2, or many in each cell, attached to hooked placental processes, exalbumi-

Botany.

Botany. nous. Chiefly tropical plants, some of them, as Justicia Ruellia, Aphelandra, and Hexacentris, remarkable for the beauty of their flowers. The lobed and sinuated leaves of Acanthus furnished the ornaments of the Corinthian

Nat. Ord. 167.—LENTIBULARIACEÆ, the Bladderwort order.—Herbs growing in water or in wet places, with radical leaves which are either undivided or cut into filiform root-like segments bearing little bladders, and irregular showy flowers. Calyx divided, persistent. Corolla bilabiate, irregular. Stamens 2, included; anthers 1-celled. Ovary superior, 1-celled; placenta free, central; ovules ∞. Fruit a 1-celled capsule. Seeds exalbuminous. Found in various parts of the world, most abundant in the tropics. The name Butterwort, applied to Pinguicula, is said to indicate its property of giving consistence to milk.

Nat. Ord. 168.—Primulaceæ, the Primrose order (Figs. 524 and 525).—Herbs with opposite, or alternate, or whorled, exstipulate leaves, and flowers often on scapes. Calyx 5-cleft, rarely 4-cleft, regular, persistent. Corolla regular, 5 or 4-cleft, very rarely 0 (as in Glaux). Stamens opposite the corolline segments (Fig. 525). Ovary superior, 1-celled, with a free central placenta; style 1; stigma capitate (Fig. 274); ovules mostly indefinite, and amphitropal. Fruit a capsule opening by valves or a lid. Seeds peltate, albuminous; embryo straight, transverse. plants abound in cold and in northern regions. Sedative, diaphoretic, and even drastic purgative plants are found in this order. Under the genus Primula are included the various species of Primrose, Cowslip, Oxlip, and Auricula.

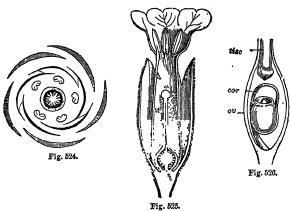

Fig. 524. Diagram of the flower of Cyclamen curopæum, Sowbread, showing 5 imbricate divisions of the calyx, 5 contorted divisions of the corolla, 5 stamens opposite the corolline segments, and a 1-celled pisth, with a free central placents, and numerous ovules.

525. Vertical section of the flower of Frimula, showing calyx, corolla, epicorolline stamens, pisth with unlocular ovary, single style and capatite stame.

capitate stigma.

... 526. Ovary of Armona mantama. Sea-pink, cut vertically; showing the ovule, ou, with its coverings, suspended by a cord or funiculus, cor, which rises from the bottom of the cell. The conducting tissue of the style, tisc, passes for a certain extent into the ovary.

Nat. Ord. 169.—Plumbaginaceæ, the Leadwort order (Fig. 526).—Herbs or undershrubs, with alternate or clustered, entire, exstipulate leaves, which are somewhat sheathing, and flowers in panicles or in heads. Calyx tubular, plaited, persistent. Corolla salver-shaped, with a 5-parted limb, or composed of 5 unguiculate petals. Stamens opposite the lobes of the gamopetalous corolla, and hypogynous or attached to the claws of the polypetalous corolla. Ovary superior, 1-celled, with a single ovule pendulous from a long funiculus which arises from the base of the cell (Fig. 526); styles 5, separate or partially united. Fruit a utricle, or opening by 5 valves. Seed inverted, albuminous. Found in salt marshes and on the sea-coasts of temperate regions; some are tropical. The species have tonic, astringent, and acrid properties; some cause blistering. Plumbago europæa, Toothwort, is used for toothache.

Nat. Ord. 170.—Plantaginaceæ, the Ribgrass order. (Fig. 164).—Herbs having usually ribbed and radical leaves, with spiked, occasionally unisexual flowers. Calyx 4parted, persistent. Corolla scarious and persistent, 4-parted. Stamens 4, alternate with the corolline segments; filaments long and slender. Ovary of one carpel, 2 rarely 4-celled by placental prolongations; style 1. Fruit a membranous pyxis with a free placenta. Seeds 1, 2, or many, albuminous. The plants are generally distributed, but are chiefly natives of temperate climates. They have bitter and astringent properties. The seeds of some are demulcent.

Note.—In the natural orders Oleaceæ and Primulaceæ, apetalous and even achlamydeous species are met with, which therefore belong properly to the sub-class Monochlamydee. Among Ericaceæ, Pyrolaceæ, Monotropaceæ, Epacridaceæ, Primulaceæ, and Plumbaginaceæ, there occur polypetalous species with hypogynous stamens, which consequently belong properly to the sub-class Thalamifloræ.

SUB-CLASS IV. MONOCHLAMYDEÆ OR APETALÆ.

1. Angiospermæ.

a. Spermogenæ.—Having true Seeds with a Dicotyledonous Embryo.

Nat. Ord. 171.—NYCTAGINACEÆ, the Marvel of Peru order.—Herbs or shrubs, with opposite leaves, and involucrate, often showy flowers. Perianth tubular and funnelshaped, the limb plaited, coloured, and separating from the hardened base, which incloses the one-celled utricular fruit, and appears to be incorporated with it. Stamens hypogynous, 1-20. Embryo coiled round mealy albumen. Natives of warm regions. Their roots are purgative, as seen in the case of Mirabilis Jalapo.

Nat. Ord. 172.—AMARANTHACEÆ, the Amaranth order. -Herbs or shrubs, with opposite or alternate, exstipulate leaves, and capitate or spiked, bracteated coloured flowers, which are occasionally unisexual. Perianth of 3-5 scarious sepals. Stamens 5, hypogynous, distinct or monadelphous; anthers often 1-celled. In other respects resembling Chenopodiaceæ. Most common within the tropics. They have mucilaginous properties. Some are used as pot-herbs, and many of them are cultivated on account of their dry, persistent, and finely coloured bracts and perianth. Amaranths are known in gardens by the name of Princes Feather (Amaranthus hypochondriacus) and Love-lies-bleeding (A. caudatus). Celosia cristata, the Cockscomb, has astringent

Nat. Ord. 173.—CHENOPODIACEÆ, the Goosefoot order (Fig. 178).—Herbs or undershrubs, with exstipulate, alternate, and occasionally opposite leaves, and small herbaceous, often unisexual flowers. Perianth divided deeply, sometimes tubular at the base, persistent. Stamens inserted into the base of the perianth, and opposite to its divisions. Ovary free, 1-celled, with a single ovule attached to its base. Fruit a utricle or achene, sometimes succulent. Embryo coiled round mealy albumen, or spiral without albumen. Inconspicuous plants, found in waste places in various parts of the world, chiefly in extra-tropical regions. Many of the plants of this order are used as pot-herbs, for instance, Spinage, Garden Orach, and Beet. Soda is supplied by some of the species of Salicornia and Salsola growing on the sea-shore. Anthelmintic and antispasmodic properties are also met with in the order.

Nat. Ord. 174.—Basellaceæ, the Basella order.—A small order of climbing, herbaceous, and shrubby tropical plants, closely allied to Chenopodiaceæ, and differing chiefly in their coloured double perianth, and in their stamens being attached to its sides. Some species of Basella are used as

used in Peru as a substitute for the Potato.

Nat. Ord. 175.—Scleranthaceæ, the Scleranthus or Knawel order.—Inconspicuous weeds, often included among the Illecebraceæ, but differing from that order in their apetalous flowers, exstipulate leaves, hardened tube of the perianth inclosing the 1-celled fruit, and perigynous stamens. They seem to be more nearly allied to Chenopodiaceæ. They occur in barren places in various parts of the world.

Nat Ord. 176.—PHYTOLACCACEÆ, the Poke-weed order. -Herbs or undershrubs, with alternate, exstipulate, often dotted leaves, and racemose flowers. Perianth of 4-5 leaves, often petaloid. Stamens hypogynous or nearly so, indefinite, or 4-5 and then alternate with the divisions of the perianth. Ovary of 1 or many united one-seeded carpels; styles and stigmas distinct. Fruit either succulent or dry. Embryo curved round mealy albumen. Many of the plants are American. They have acrid, emetic, and purgative qualities. The berries of *Phytolacca decandra*, Poke or Pocan, yield a deep purple juice. Its root is emetic, and is used in rheumatic and syphilitic pains. The young shoots are eaten as Asparagus. Gyrostemon, a genus with unisexual flowers, is considered as a type of an allied order, Gyrostemonace a.

Nat. Ord. 177.—Petiverlaceæ, the Petiveria order. —A small order of plants separated from Phytolaccaceæ on account of their stipulate leaves, exalbuminous seeds, straight embryo, and convolute cotyledons. Tropical American plants. They have acrid properties and an alliaceous odour.

Nat. Ord. 178.—Polygonaceæ, the Buckwheat order* (Figs. 527, 528).—Herbs, rarely shrubs, with alternate

Fig. 527. Diagram of the flower of Rumex, Dock, showing a six-partite perianth, in two alternating rows, six stamens in pairs, and a one-celled ovary formed of 3 carpels.

528. Fruit of Rumex out vertically, showing the triquetrous achene closely invested by the inner segments of the perianth, two out of the three styles, and the arcuate embryo on one side of failnaceous albumen.

leaves, ochreate stipules, and occasionally unisexual flowers. Perianth often coloured. Stamens definite, and inserted into the base of the Perianth. Ovary formed of 3 carpels, 1-celled, containing a single orthotropal ovule. Fruit a triangular nut, often covered by the perianth (Fig. 528). Embryo usually on one side of mealy albumen. Generally distributed both in cold and warm climates. Acid, astringent, and purgative qualities are met with in the plants of this order. Fagopyrum esculentum, and other species, are cultivated as Buckwheat. Polygonum Bistoria* has a twisted rhizome, which is used as an astringent. Various species of Rheum yield the different kinds of Rhubarb. R. palmatum is generally said to be the plant which supplies Russian or Turkey Rhubarb.

Nat. Ord. 179.—Begoniaceæ, the Begonia order.— Herbs or succulent undershrubs, with alternate oblique stipulate leaves, and cymose, pink, unisexual flowers. Perianth superior, coloured, with 4 divisions in the male flower, and 5-8 in the female. Stamens ∞, distinct or united; anthers collected into a head. Ovary winged, 3-celled, with 3 placentas meeting in the axis. Fruit capsular, winged, 3celled. Seeds co, exalbuminous, reticulated. Found in the East and West Indies, and in South America. They are said, to have bitter and astringent qualities. Begonias

Botany. Spinage. Melloca tuberosa has a tuberous root, which is their oblique leaves. Their succulent stalks are sometimes Botany. used like Rhubarb.

Nat. Ord. 180.—LAURACEÆ, the Laurel order (Figs. 529, 530).—Trees with exstipulate, usually alternate, dotted

Perianth leaves. 4-cleft, or 6-cleft in 2 rows. Stamens often 8-12, the 3 or 4 innermost being abortive staminodia, and the outer fertile; filaments sometimes bearing glands, anthers 2-4-celled, opening by revalves. curved Ovary superior, 1celled, with 1 or 2 pendulous ovules. Fruit a berry or

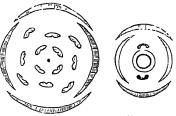

Fig. 529. Fig. 530. Fig. 529. Fig. 530.

Fig. 529. Diagram of the male or stammiferous flower of Laurus nobils, Sweet Bay, showing four divisions of the perianth, twelve stamens in three rows, some fettile, some abortive, and the abortive pital as a point in the centre.

... 530. Diagram of the female or pistiliferous flower of Laurus nobilis, showing a four-divided perianth, and a one-celled ovary in the centre, with two abortive stamens.

stamens.

drupe; pedicel often thickened; seed solitary, exalbuminous; embryo with large cotyledons. Tropical aromatic and fragrant plants, yielding fixed as well as volatile oils and camphor. Some have tonic and febrifugal barks; others supply edible fruits. The timber of some of the plants is valuable. Camphora officinarum, a tree found in China and Japan, supplies camphor. Cinnamomum zeylanicum, is the Cinnamon-tree, the bark of which constitutes the Cinnamon of commerce. Laurus nobilis, Sweet-bay, yields a concrete green oil, called Oil of Bays. Its branches were used to crown the victors in the ancient games. Nectandra Rodiæi (N. leucantha, var. N. ab. E.), yields the Bebeerubark, which contains an antiperiodic alkaloid Bebeerine. Its wood is called Green-heart, and is used in ship-building.

Nat. Ord. 181.—ATHEROSPERMACEÆ, the Plume-Nutmeg order.—Trees, with opposite exstipulate leaves, and bracteated unisexual flowers. Perianth tubular, divided at the top into segments, in 2 rows, the inner partly petaloid. Stamens numerous, inserted in the bottom of the perianth; filaments with scales at their base; anthers with valvular dehiscence. In the female flowers, there are often abortive stamens in the form of scales. Carpels numerous, each having a single erect ovule. Fruit achenes, inclosed in the tube of the perianth, having persistent feathery styles. Seed solitary, erect; embryo minute in the base of fleshy albu-

men. Fragrant plants from Australia and Chili. Nat. Ord. 182.—MYRISTICACEÆ, the Nutmeg order.*—*Plate. Tropical trees, with alternate, exstipulate leaves, and uni-CXXXL sexual flowers. Perianth 3-4-cleft, valvate. Stamens 3-12, distinct or monadelphous; anthers extrorse, often united. In the female flowers, the perianth is deciduous. Carpels 1 or many, each with a single erect anatropal ovule. Fruit succulent, 2-valved. Albumen ruminate. Some regard this order as an apetalous unisexual form of Anonaceæ. Natives of the tropical parts of India and America. The plants of this order are acrid and aromatic. Their bark yields a red juice. Myristica moschata* is the Nutmeg-*Plate tree of the Moluccas. The fruit is drupaceous and dehisces, CXXXL so as to display the scarlet mace, which consists of a reticulated arillode covering the shell in which the seed or

Nutmeg is inclosed. Nat. Ord. 183.—MONIMIAGEÆ, the Monimia order.— Trees or shrubs, with opposite, exstipulate leaves, and unisexual flowers, resembling Atherospermaceæ, from which they differ chiefly in the anthers dehiscing longitudinally, in the ovule being pendulous, and in the want of feathery styles to the fruit. The plants are chiefly South American, and possess aromatic qualities.

Nat. Ord. 184.—PROTEACEÆ, the Protea order.—Shrubs receive the name of Elephant's-ear from the appearance of or small trees, with hard, dry, exstipulate leaves. Perianth

*Plate CXXX.

*Plate

CXXX

Botany.

Botany. divided into 4, valvate. Stamens 4, placed on the segments of the perianth. Ovary of one superior carpel, containing 1 or more ovules; fruit dehiscent or closed. Seed exalbuminous; embryo straight. Natives of Australia and the Cape of Good Hope chiefly. Leucadendron argenteum is the Witteboom or Silver-tree of the Cape. Protea grandiflora is called Wagenboom.

> Nat. Ord. 185.—ELEAGNACEE, the Oleaster order.— Trees or shrubs, usually lepidote, with exstipulate leaves, and unisexual, rarely hermaphrodite, flowers. Male flowers in the axil of scales; perianth of 2-4 leaves, sometimes united; stamens 3, 4, or 8. In the Ω and Ω flowers, perianth tubular, with a fleshy disk. Ovary free, 1-celled, with a single ascending ovule. Fruit a crustaceous achene, inclosed in the succulent perianth. Found chiefly in the northern hemisphere. Many are cultivated for their silvery scaly foliage. The scales are beautiful microscopic objects (Fig. 53). Hippophaë rhamnoides, Sea Buckthorn, is a spiny plant which thrives on the sea-shore. Elæagnus parvifolia, small-leaved Oleaster, bears clusters of red edible berries, mottled with scales.

> Nat. Ord. 186.—Penæaceæ, the Penæa order.—Shrubs. with opposite exstipulate leaves. Perianth inferior, bracteated, salver-shaped, limb 4-lobed. Stamens 4 or 8, inserted on the perianth. Ovary 4-celled, with 4 appendaged stigmas. Fruit a 4-celled capsule. Seed exalbuminous; embryo with minute cotyledons. Evergreens, found at the Cape of Good Hope. Some yield a gum-resin called Sarcocol.

> Nat. Ord. 187.—THYMELEACEE, the Mezereon order. —Shrubby plants, with stipulate leaves, and ♥ rarely ₺♀ flowers: Perianth coloured, tubular, with a 4-5-lobed imbricate limb. Stamens often twice as many as the lobes of the perianth, and inserted on its tube. Carpel solitary, superior, with a single pendulous ovule. Fruit nut-like or drupaceous. Seed with or without albumen; embryo straight. Natives both of cold and of warm climates in various parts of the world. The plants of this order possess acrid, irritant, and occasionally narcotic qualities. The bark of many of them is tough and tenacious, so as to be used for cordage. Daphne cannabina has a fibrous inner bark, which is used for ropes and for the manufacture of paper. Lagetta lintearia is called Lace-bark tree, on account of the beautiful meshes of its inner bark.

> Nat. Ord. 188.—AQUILARIACEÆ, the Aquilaria order.— Trees, with exstipulate leaves. Perianth tubular, with a 4-5-lobed imbricate limb. Stamens usually 8-10, inserted into the throat of the perianth. Ovary superior, 2-celled, with 2 suspended ovules. Fruit a 2-valved capsule, or succulent. Seeds exalbuminous. Natives of the tropical parts of Asia. Some of the plants yield resinous matter, which is used as a stimulant.

> Nat. Ord. 189.—Samydaceæ, the Samyda order.— Trees or shrubs, with alternate, stipulate, usually dotted leaves. Perianth 4-5-parted; æstivation imbricate. Stamens inserted into the tube of the perianth, 2, 3, or 4 times as many as its divisions, some of them occasionally sterile; filaments united. Ovary superior, 1-celled, with numerous ovules. Fruit, a leathery, 1-celled, 3-5-valved capsule. Seeds albuminous, arillate, attached to parietal placentas. Tropical, chiefly American plants, with astringent bark and leaves.

Nat. Ord. 190.—Santalaceæ, the Sandal-wood order. -Trees, shrubs, or herbs, with alternate, entire, exstipulate leaves, and small flowers, sometimes & Q. Perianth adherent, 4-5-cleft, valvate. Stamens 4-5, inserted into the throat of the perianth opposite its segments. Ovary 1celled; ovules 1-4; placenta central. Fruit monospermal, dry, or succulent. Seed albuminous. Found in Europe, Asia, America, and Australia. Some of the species are astringent, others yield edible fruit. The wood is in some

instances fragrant, and the bark is tough and tenacious. Santalum album, a Malabar tree, from 25 to 30 feet high, produces Sandal-wood, which is used as a perfume in China, and in India as an astringent.

Nat. Ord. 191.—Aristolochiaceæ, the Birthwort order (Fig. 531).—Herbs or climbing shrubby plants, with alternate leaves, solitary or clustered brown or greenish coloured \$ flowers, and wood arranged in separable wedges. Perianth tubular (Fig. 383), adherent, valvate. Stamens 6-12, epigynous, distinct or adherent to the style and stigmas (Fig. 248). Ovary 3-6-celled; ovules ∞ ; stigmas radiating. Fruit a 3-6-celled polyspermal capsule or berry. Seeds albuminous; embryo minute. Found in various parts of the world, but abundant in the tropical parts of South America. Birthworts have pungent, aromatic, stimulant, and tonic properties. Some have been celebrated for their effects on the uterus, others as antidotes for snakebites. The root of various species of Aristolochia have been used as emmenagogues. The root of A. serpentaria, Virginian Snake-root, formerly of repute in typhus fever, and also in cases of snake-bite, is a valuable stomachic.

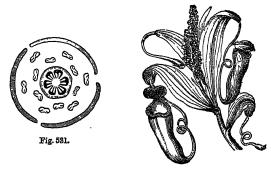

Fig. 532.

Fig. 531. Diagram of the flower of Asarum europæum, Asarabacca, showing three divisions of the perianth, nine stamens in three rows, and a three-celled ovary.

... 552. Flowering branch of Nepenthes distillatoria, the Pitcher-plant. The racemose flowers are seen with the operculate ascidia at the end of the leaves.

Nat. Ord. 192.—NEPENTHACEÆ, the Pitcher-plant order (Fig. 532).—Herbaceous or suffruticose plants, with alternate leaves, having calyptrimorphous ascidia at their extremities (Fig. 140), wood in separable wedges, and racemose diœcious flowers. Perianth inferior, 4-leaved, imbricate. Stamens columnar, with anthers collected into a Ovary superior, tetragonal, 4-celled; ovules ∞ ; ascending. Fruit a 4-celled, 4-valved capsule, loculicidal. Seeds with a loose testa, albuminous. Found in marshy ground in the East Indies and China.

Nat. Ord. 193.—Datiscaceæ, the Datisca order.-Herbs or trees, with alternate exstipulate leaves, and 5 2 flowers. Perianth, 3-4 divided, adherent to the ovary. Stamens 3-7, ovary unilocular, with 3-4 polyspermous parietal placentas. Fruit a 1-celled capsule opening at the apex. Seeds strophiolate, exalbuminous. The plants are scattered over various parts of the world, chiefly in the northern hemisphere. Bitter and purgative properties are met with in the order. Some yield fibres.

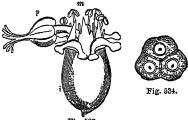

Nat. Ord. 194.—EMPETRACEÆ, the Crowberry order.— Shrubs, with heath-like, evergreen, exstipulate leaves, and small axillary unisexual flowers. Perianth of 4-6 hypogynous persistent scales, the innermost sometimes petaloid and united. Stamens 2-3, alternate with the inner row of scales. Ovary free, on a fleshy disk, 2-9-celled; ovules solitary. Fruit fleshy, with 2-9 nucules. Seed solitary, ascending; embryo with an inferior radicle. A small group, allied to Euphorbiaceæ, and distinguished chiefly by its ascending seeds and inferior radicle. Natives chiefly of the northern parts of Europe and America. Their leaves

Botany. *Plate CXXXII.

and fruit are often subacid. Empetrum nigrum, Crowberry, has black watery fruit.

Nat. Ord. 195.—EUPHORBIACEÆ, the Spurgewort order*

(Figs. 533, 534).--Trees, shrubs, or herbs, with opposite or alternate, often stipulate leaves, and involucrate (Fig. 533), unisexual, sometimes, achlamydeous flowers (Fig. 209). Peri-

(Fig. 209). Perianth, when present, fig. 533. Involuce, 4, of Enphorbia, containing inferior, lobed, with glandular, scaly, or petaloid appendaments. Saly, or petaloid appendaments. Saly, Section of tricoccons fruit of Euphorbia.

ages. Stamens definite or ∞, separate (Fig. 246), or united in one or more bundles (Fig. 251). Ovary 1, 2, or 3 or more celled; ovules 1 or 2, suspended. Fruit usually tricoccous (Fig. 534), the carpels separating with elasticity, sometimes fleshy and indehiscent. Seeds albuminous, often arillate. Embryo with a superior radicle. Lindley considers this a dichlamydeous order, and as becoming monochlamydeous or achlamydeous by abortion. The plants abound in equinoctial America. Some are found in North America, Africa, India, and Europe. The plants of the order are generally acrid and poisonous, abounding in a milky juice. Starchy matter is procured from many of the species, as well as oils and caoutchouc. Croton Eleuteria produces a tonic bark known by the name of Cascarilla. The seeds of C. Tiglium yield, by expression, Croton-oil, which is a drastic purgative in doses of one or two drops. Euphorbia Lathyris, Caper-spurge, has been used as a purgative. E. officinarum is the source of the purgative resin *Pl. CXIII. called Euphorbium. Janipha Manihot* is the Cassava or Manioc plant. Oldfieldia africana is the tree which supplies the African Teak. The seeds of Ricinus communis yield Castor-oil by expression.

Nat. Ord. 196.—Scepaceæ, the Scepa order.—Trees, with alternate stipulate leaves and unisexual flowers, resembling Euphorbiaceæ, and differing chiefly in being amentiferous. The perianth is 4, 5, or 6-leaved; stamens 2-5; ovary 2-celled, ovules in pairs; seeds arillate, often buried in hairs. Natives of India.

Nat. Ord. 197.—CALLITRICHACEÆ, the Starwort order. -Aquatic herbs, with opposite leaves, and minute axillary unisexual achlamydeous flowers. Stamen 1, rarely 2; anther reniform, 1-celled. Ovary solitary, tetragonal, 4-celled; ovules solitary in each cell; styles 2. Fruit 4-celled, 4seeded, indehiscent. Seeds peltate, albuminous; embryo

with a superior radicle. Natives of still waters in Europe and North America.

Nat. Ord. 198.— CERA-TOPHYLLACEÆ, the Hornwort order.-Aquatic herbs, with verticillate leaves and monœcious flowers. Perianth inferior, 10-12-cleft; anthers sessile, 12-20; ovary 1-celled, sessile, 12-20; ovary 1-celled, with 1 pendulous ovule. Fruit an achene; seed exalbuminous; embryo with an inferior radicle. Found in ditches in various parts of the world.

Nat. Ord. 199.—URTICA-CEE, the Nettle and Hemporder (Figs. 535, 536).—
Trees, shrubs, or herbs, with

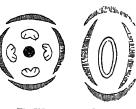

Fig. 535. Fig. 536.

watery juice and alternate stipulate leaves, often covered

with asperities or stinging hairs (Fig. 48). Flowers uni- Botany. sexual, rarely \$\varphi\$, scattered or collected into heads or catkins. Perianth divided; stamens definite, opposite the lobes of the perianth, and inserted into its base; filaments sometimes curved and elastic (Fig. 378); ovary superior, 1-celled, with a solitary ovule; fruit indehiscent, with a single seed. Embryo straight, hooked, or spiral, with or without albumen; radicle superior. Natives chiefly of temperate regions. Some of the plants have caustic juice connected with stinging hairs; others yield valuable fibres. Occasionally narcotic qualities are present. Böhmeria nivea supplies the fibres whence Chinese grass-cloth is made. Cannabis sativa, is the common Hemp plant. An Indian variety, C. indica, possesses powerful narcotic qualities. Humulus Lupulus, the Hop, is cultivated on account of its bitter principle, Lupulin, which exists in the resinous scales (Fig. 54) surrounding the fruit.

Nat. Ord. 200.—Artocarpaceæ, the Bread-fruit* and *Plate CXXXIII.

Fig. 537. Male flower of Morus nigra, Black Mulberry, showing four stamens opposite the four segments of the perianth, and the rudimentary, pistil in the centre.

... 538. Fruit of the Mulberry, consisting of numerous female flowers united into a succulent mass. It is a polygynæcial or anthocarpous fruit.

Mulberry order (Figs. 537, 538).—Trees or shrubs, with a milky juice, and alternate lobed leaves, having large stipules. The flowers are 5 2, and are collected into dense heads or catkins. The plants are considered by many as a section of Urticaceæ, from which they differ chiefly in being lactescent, in their fruit being a sorosis (Fig. 326), or syconus (Fig. 157). Perianth divided (Fig. 537), often wanting; ovary 1-celled; ovules erect or pendulous. Fruit polygynœcial or anthocarpous, consisting of achenes immersed in the persistent fleshy perianths (Fig. 538), or situated upon (Fig. 156) or within large fleshy receptacles (Fig. 157). Seeds albuminous or exalbuminous; embryo straight or hooked. The plants of this order supply, in many instances, edible fruits; their milky juice often abounds in caoutchouc, and, in some instances, is bland and nutritious, while their inner bark supplies fibres. Bitter, tonic, as well as acrid and poisonous properties, are found in the order. Antiaris toxicaria is a large tree, whence the Javanese poison called Upas-Antiar is obtained, and which owes its activity to a peculiar principle Antiarin. Artocarpus incisa,* the *Plate Bread-fruit tree (Fig. 326), has large pinnatifid leaves, CXXXIII.

while A. integrifolia, the Jack-fruit, has undivided leaves. Galactodendron utile, the Cow-tree of South America, has a nutritive milky juice. Dorstenia Contrayerva, and other species (Fig. 156), have a stimulant, tonic, and diaphoretic rhizome. Ficus Carica, the common Fig (Fig. 157), is used as a laxative and as a cataplasm. Urostigma (Ficus) elasticum, and other species, supply caoutchouc abundantly. U. indicum (benghalense) is the Banyan-tree of India (Fig. 65).

Nat. Ord. 201.—Ulmaceæ, the Elm order.—Trees or shrubs, with scabrous, alternate, stipuled leaves, and g or ₹ ? flowers in loose clusters. Perianth inferior, membranous, campanulate, irregular. Stamens definite, attached to the base of the perianth. Ovary 1-2-celled; ovules solitary, pendulous; stigmas 2. Fruit 1 or 2-celled, indehiscent. dry, or drupaceous. Seed solitary, without or with little albumen. Bitter and astringent properties exist in the bark and fruit of some of the plants of this order. Many are valuable timber-trees.

Nat. Ord. 202.—Stillagnaceæ, the Stilagoorder.—Trees or shrubs, with alternate, stipuled leaves, and minute 5 ? flowers in scaly spikes. They are allied to Urticaceæ, and are chiefly distinguished by their large disk and vertical antherine cells, opening transversely, and having a fleshy connective. Their fruit is drupaceous, and seed suspended and albuminous. Natives of the East Indies and of Mada-

Nat. Ord. 203.—LACISTEMACEÆ, the Lacistema order.— Shrubs, with alternate, simple stipuled leaves, and 덫 or ᄎ오 flowers in axillary catkins. Perianth free, divided, with a large bract. Stamen 1, hypogynous; connective separating antherine cells, which open transversely. Disk often fleshy. Ovary 1-celled; placentas parietal. Fruit a 1-celled 2-3-valved capsule, loculicidal. Seeds suspended, arillate, albuminous. Natives of the tropical woods of America.

Nat. Ord. 204.—Podostemonaceæ, the River-weed order.—Submersed aquatic herbs, with capillary or minute leaves, which are often densely imbricated. They have the aspect of Mosses or Liverworts. Flowers usually &. Perianth imperfect or 0, sometimes of 3 parts. with a spathe. Stamens 1, or many, hypogynous. Ovary 2-3-celled; placenta parietal or axile. Fruit a 2-3-valved capsule. Seeds numerous, exalbuminous; embryo orthotropal. Chiefly natives of South America. Some of the species are used for food.

Nat. Ord. 205.—CHLORANTHACEÆ, the Chloranthus order.—Herbs or undershrubs, with jointed stems, opposite simple leaves, sheathing petioles, interpetiolar stipules, and spiked of or \$2 flowers. Scaly bract, no perianth. Stamens definite, lateral, 1 or more; anthers 1-2-celled, with a fleshy connective. Ovary 1-celled; ovule orthotropal. Fruit drupaceous. Seed pendulous; embryo minute, at the apex of fleshy albumen; no vitellus. Natives of the warm regions of India and America chiefly. They have aromatic and stimulant properties. The leaves of *Chloranthus in*conspicuus are sometimes used to perfume tea.

Nat. Ord. 206.—SAURURACEÆ, the Lizard's-tail order.-Marshy herbs, with alternate, stipuled leaves, ♂ spiked flowers, each supported on a scale. Perianth 0. Stamens 3-6, hypogynous, club-shaped, persistent. Ovaries 3-4, distinct or united. Ovules few, orthotropal. Fruit of 4 achenes, or a 3-4-celled capsule. Embryo in a vitellus, outside mealy albumen, at the apex of the seed. Natives of North America, China, and Northern India.

Nat. Ord. 207.—PIPERACEÆ, the Pepper order (Figs. 539 and 540).—Shrubs or herbs with jointed stems, usually

Fig. 540.

Fig. 539. Branch of Piper longum, a species of Charica, perhaps C. Roxburghii, showing its spiked female flowers, which, when dried, constitute Long Pepper. The leaves are cordate acute. Charica perpuloides and C. officinarum, also supply the officinal Long Pepper, according to Miquel.

... 540. Piper nigrum, the plant which yields Black and White Pepper, with its spiked flowers and cordate acuminate leaves.

opposite or verticillate leaves, stipules sometimes present, flowers & in spikes, each supported on a bract, no perianth. Stamens 2 or more; ovary free, 1-celled; ovule 1, erect, orthotropal. Fruit somewhat fleshy, indehiscent, 1-celled,

1-seeded. Seed erect; embryo in a vitellus or fleshy sac outside the albumen, and at the apex of the seed. The stems of Pepper have a peculiar arrangement of the woody matter in wedges and not in concentric zones. Natives of tropical regions, especially in America and Asia. The plants of this order are pungent and aromatic, owing to the presence of an acrid resin, an oil, and a crystalline matter called Piperin. Some possess narcotic qualities, others are astringent. Chavica Roxburghii, and other species (Fig. 539), produce Long-pepper, which is the dried female spikes. Cubeba officinalis, and other species, produce the aromatic pungent fruit called Cubebs. Piper nigrum (Fig. 540) is a climbing East Indian plant, the dried unripe fruit of which constitutes Black Pepper.

Nat. Ord. 208.—MYRICACEÆ, the Gale order (Fig. 541). -Amentiferous shrubs or small trees, with resinous glands, alternate leaves, and unisexual flowers. Perianth O. Stamens 2-8, usually in the axil of a bract; anthers 2-4-celled. Ovary 1-celled, with hypogynous scales; ovule solitary, orthotropal; stigmas 2. Fruit drupaceous, often covered with wax, and with adherent fleshy scales. Seed solitary, erect, exalbuminous; embryo with superior radicle. Found both in temperate and in tropical countries. plants have aromatic, tonic, and astringent properties. Tannic and benzoic acids, as well as wax, resin, and oil, are procured from different species. The berries of Myrica cerifera, Wax Myrtle or Candleberry (Fig. 541), furnish a greenish-coloured wax when put into hot water.

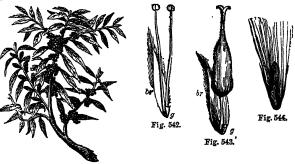

Fig. 541.

Fig. 541. Myrica cerifera, Wax Myrtle, or Candleberry bush. Its succulent fruit is covered with a waxy secretion.

... 542. Single male flower of a Willow, showing the single bract, br, bearing 2 stamens, with a gland, g, at the base. The flower is called naked or achiamydeous.

... 543. Single female flower of a Willow, with bract, br, bearing a stipitate or stalked ovary, with 2 stigmas, st, at the aummit, and a gland, g, at the base. The flower is also naked.

... 544. Comose seed of the Willow, showing the hairs proceeding from its base.

Nat. Ord. 209.—Salicaceæ, the Willow order (Figs. 542 to 544).—Amentiferous trees or shrubs (Fig. 167), with alternate, simple, stipuled leaves, sometimes with petiolary glands, and 52 flowers. Perianth 0, or cup-like. Stamens 2-30. Ovary superior, 1-celled; ovules numerous, erect, attached to the bottom of the cell, or to the base of 2 parietal placentas; stigmas 2. Fruit leathery, 1-celled, 2-valved, polyspermal. Seeds covered with basal silky hairs, exalbuminous; embryo erect, with an inferior radicle. Chiefly found in northern regions; some grow on the high mountains of South America, others in antarctic regions. The plants of this order are useful timber trees, and they are employed for various economical purposes. Their bark is tonic and astringent. The downy matter surrounding the seeds is used for stuffing cushions, and for making paper. The bark of Salix alba, S. Helix, S. purpurea, S. fragilis, S. caprea, S. pentandra, and many other species, contains a bitter tonic principle called Salicin.

Nat. Ord. 210.—Altingiaceæ or Balsamifluæ, the Liquidambar order:—Amentiferous unisexual trees, with alternate, stipuled leaves, and involucrate catkins. Anthers on, nearly sessile, with a few minute scales. Ovaries 2-

Botany. celled, collected into a round mass, each with a few scales; styles 2; ovules ∞ , amphitropal. Fruit, consisting of 2celled capsules, inclosed in scales, and forming a sort of cone. Seeds winged, peltate, albuminous; embryo inverted, radicle superior. Natives of the warmer parts of India and America; also found in the Levant. Fragrant and balsamic properties are met with in this order. The bark of some of the plants is bitter.

Nat. Ord. 211.—Betulacese, the Birch order (Fig. 545). -Amentiferous trees or shrubs, with alternate, simple, stipuled, often feather-veined leaves, and unisexual flowers, which have small scales in place of a perianth. Stamens opposite the scales. Ovary 2-celled; ovules 1 in each cell, pendulous, anatropal; stigmas 2. Fruit dry, indehiscent, 1celled, 1-seeded. Seed exalbuminous; radicle superior. In Alnus there is a 4-leaved membranous perianth. The plants of this order are usually timber trees, such as the Birch and Alder, with deciduous leaves, chiefly found in northern and cold regions. Their bark is tonic and astrin-

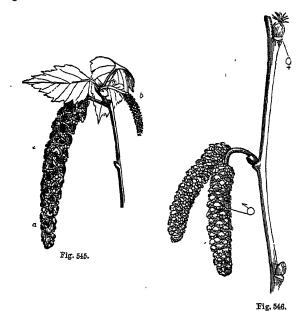

Fig. 545. Betula alba, the common Birch. Its male flowers, a, are produced in scaly catkins, and they have no proper perianth; its female flowers, b, are in scaly spikes or catkins, and are also naked.

546. Flowering branch of Corylus Avellana, the Hazel or Hasel, bearing male flowers t in catkins (amentiferous), and female flowers Q in rounded clusters.

Nat. Ord. 212.—Corylace or Cupulifere, the Hazel and Oak order (Fig 546).—Amentiferous trees or shrubs, with simple, alternate, stipulate, often feather-veined leaves, and monœcious flowers (Fig. 546). Barren flowers in catkins. Stamens 5-20, inserted in the base of scales, or of a membranous valvate perianth. Fertile flowers aggregate (Fig. 546, ♀), or on a spike. Ovary, with several cells, crowned by the remains of an adherent perianth inclosed in an involucre or cupula (Fig. 299). Ovules in pairs or solitary, pendulous or peltate; stigmas several. Fruit a glans (Fig. 300); seed solitary, exalbuminous. The plants abound in the forests of temperate regions in the form of Oaks, Hazels, Beeches, and Chestnuts. The plants of this order afford valuable timber and edible seeds. Astringency also prevails in a marked degree in the bark.

Nat. Ord. 213.—Casuarinaceæ, the Beefwood order.— Leafless trees, with pendulous, jointed, striated, sheathed branches, and spikes or heads of unisexual flowers proceeding from bracts. Barren flowers in spikes, and whorled round a jointed rachis. Perianth 2-leaved, with 2 alternating bracts. Stamen 1, carrying up the united 2 leaves of

the perianth in the form of a lid. Fertile flowers, capitate, Botany. without a jointed rachis, and naked. Ovary 1-celled; ovules 1 or 2, orthotropal; styles 2. Fruit, winged achenes, combined into a bracteated cone. Seed exalbuminous; epi-sperm with spiral cells; radicle superior. Tropical or subtropical plants, having the aspect of Equisetums. They abound in Australia. Their wood is hard and heavy, and on account of its colour is called Beefwood. The bark of some of the species of Casuarina is tonic and astringent.

Nat. Ord. 214.—PLATANACEE, the Plane order (Fig.

547).—Amentiferous trees or shrubs, with alternate, deciduous, palmate, or toothed, stipulate leaves, and unisexual naked flowers in globose catkins (Fig. 547). Barren flowers. single, Stamens mixed with scales. Fertile flowers. Ovary 1-celled; style thick and subulate. Ovules 1-2, orthotropal, suspended. Nuts cla-

vate, with a per-Branch of Platanus orientalis, showing the globose sistent style. Seeds clusters or catkins of female flowers.

usually solitary and albuminous: radicle inferior. Natives of the Levant and North America chiefly. The species of Platanus are fine trees, but their timber is not durable.

Nat. Ord. 215.—JUGLANDACEÆ, the Walnut order (Fig.

548).—Trees, with alternate, pinnate, stipuled leaves, and unisexual flowers. 5: Amentiferous. Perianth 2-3-6parted, with a scaly bract. Stamens 3 or more. 2: In terminal clusters or in loose racemes, with distinct or united bracts. Perianth adherent, 3-5-divided. Ovary 2-4-celled at the base, unilocular at the apex. Ovule solitary, orthotropal, and erect; style 1 or 2. Fruit solitary, a tryma, endocarp stony and often 2-valved. Seed exalbuminous, 2-4-lobed at the base, and partly divided by partial dissepiments. Natives chiefly of North America. Some are found in the East Indies, Persia, and the Caucasus. The plants are fine trees with edible oily seeds and an acrid bark. Purgative

Branch of Juglans regia, the Walnuttree, with an impari-pinnate leaf and a cluster of drupaceous fruit.

Fig. 548.

qualities are found in some of the species. , Carya alba, the common Hickory-tree, produces an eatable nut. Juglans regia is the Walnut-tree (Fig. 548).

Nat. Ord. 216.—GARRYACEÆ, the Garrya order.— Shrubs with opposite, exstipulate leaves, and amentiferous unisexual flowers, surrounded by united bracts. 5: Perianth of 4 leaves, alternating with 4 stamens. Q: Perianth adherent, bidentate. Ovary 1-celled styles 2; ovules 2, pendulous with long cords. Fruit a 2-seeded berry. Embryo minute in the base of fleshy albumen. The wood is not arranged in circles, and there is an absence of dotted vessels. Natives chiefly of the temperate parts of America. b. Sporogenæ or Rhizanthæ.—Having Spore-like Seeds with an Acotyledonous Embryo.

Nat. Ord. 217.—RAFFLESIACEÆ, the Rafflesia order (Fig.

549).—Stemless and leafless parasites, consisting only of ♥ or ★:♀ flowers growing on the branches of trees. Perianth superior, with a 5-parted limb, thickened processes or calli, either distinct or united

into a ring, being attached to the throat of the tube.

The essential or-

gans are combined in a column (synema) which adheres to the tube of the perianth. Anthers 2-celled, either distinct and opening by vertical apertures, or combined together, so as to become a multicellular mass opening by a common pore. Ovary 1-celled, placentas parietal. Fruit indehiscent. Seeds &; embryo cellular, undivided. East Indian and South American plants, parasitic on species of Cissus and on some Leguminosæ.

Nat. Ord. 218.—CYTINACEÆ, the Cistus-rape order.— Root-parasites, having ♥ or ਰ ♀ flowers, which are either solitary and stemless, or proceed from bracts arising from a scaly stalk. Perianth has a tubular form, and a 3-6-lobed limb. Anthers sessile, 2-celled, opening longitudinally. Ovary inferior, 1-celled; placentas parietal. Fruit containing pulp. Seeds ∞, immersed in pulp, and with a leathery covering; embryo undivided. Natives of the south of Europe and the Cape of Good Hope. Parasitical on the roots of Cistus, and on those of some succulent plants.

Nat. Ord. 219.—BALANOPHORACEÆ, the Balanophora order.—Leafless root-parasites, with tubers or rhizomes. whence proceed naked or scaly peduncles, bearing heads of unisexual bracteated flowers, mixed with filaments. 5: Flowers generally white. Perianth tubular, 3-5-lobed or entire. Stamens 3-5, rarely 1; anthers free or united into a multicellular mass. Q: Perianth having its tube closely investing the ovary, and its limb 0 or bilabiate; rarely 6leaved. Ovary 1-celled; ovule a pendulous, cellular nucleus; styles 1-2. Fruit somewhat drupaceous. Seed solitary, albuminous; embryo undivided. Parasitic on the roots of various Dicotyledons, and abounding on the mountains of tropical countries, especially the Andes and Himalava.

2. Gymnospermæ or Gymnogenæ.

Nat. Ord. 220.—Conferæ or Pinaceæ, the Conferous or Pine order (Figs. 550 to 553).—Resinous trees or shrubs. with disk-bearing woody tissue (Fig. 550), linear, accrose or 'anceolate, parallel-veined leaves, sometimes clustered and having a membranous sheath at the base (Fig. 551); flowers unisexual and achlamydeous. Male flowers in deciduous catkins, each consisting of 1 stamen or of several united; anthers 2 or many-celled, dehiscing longitudinally, often crested above (Fig. 552). Female flowers in cones; scales arising from the axil of membranous bracts supplying the place of ovaries; no style nor stigma; ovules naked, 1, 2, or several, at the base of each scale, with a large micropyle at the apex (Fig. 296). Fruit a cone formed of hardened scales, sometimes with the addition of bracts also, which either disappear, or become enlarged and lobed. Seed with a hard crustaceous spermoderm, sometimes winged (Figs. 553 and 328); embryo in fleshy oily albumen, sometimes poly-VOL V.

cotyledonous (Fig. 341); radicle having no definite boun- Botany. dary, but losing itself among the lax cells of the albumen near the apex of the seed. Conifers are found in various parts of the world, both in cold and in warm climates. They are most abundant in temperate regions, both in the northern and southern hemispheres. In the former they occur in

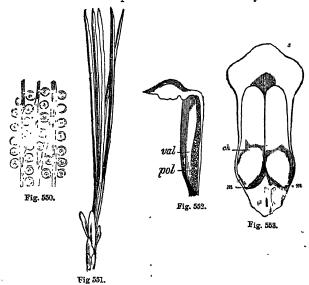

Fig. 550. Punctated or disk-bearing woody tissue of a Conifer.

... 551. Linear leaves of Pinus Strobus in a cluster of five, with a scaly sheath at the base.

... 552. Stamen of a Conifer, with longitudinal dehiscence, val, containing pollen, pol, and terminated by a crest at the apex.

... 558. Scale of a mature cone, with two winged seeds at the base, the micropyle, m, and the chalaza, ch.

the form of Pines, Spruces, Larches, Cedars, and Junipers, while in the latter we meet with species of Araucaria, Eutassa, and Dammara. The two following divisions have been adopted:—Sub-order 1. Abietineæ, the Fir tribe; ovules inverted, pollen oval, or curved (Fig. 267). Suborder 2. Cupressineæ, the Cypress tribe; ovules erect, pollen spheroidal, cone occasionally succulent, forming a galbulus. Conifers supply valuable timber, and yield resin, oil, pitch, and turpentine of various kinds. Abies balsamea, the Balm of Gilead Fir, and A. canadensis, Hemlock Spruce, yield Canada Balsam. Cedrus Libani, is the Cedar of Lebanon; C. Deodara, the Deodar, is a noble Himalayan Cedar, which some have thought to be a variety of the Cedar of Lebanon. Dammara australis, is the Kaurie or Cowdie Pine of New Zealand, which attains a height of 200 feet, and supplies valuable timber for masts, as well as a hard useful resin; D. orientalis yields the Dammar resin of India. Eutassa excelsa is the famous Norfolk Island Pine, which grows to

the height of 181-224 feet, and the wood of which is very valuable. The species of Juniperus have a succulent cone called galbulus.

Nat. Ord. 221.—TAXACEÆ, the Yew order (Figs. 554 and 555). Trees or shrubs, having narrow, evergreen, alternate, or distichous leaves which are either veinless or Fig. 554. Staminiferous flower of the Yew, with bracts at the base and nullied to Coniferse, and generally inlied to Coniferæ, and generally included as a section of the order, but differing in not producing true cones. They have monadelphous stamens (Fig. 554); solitary, naked ovules, and their seed is supported on, or inclosed by, a succulent

Fig. 554. at the base and numerous monadelphous stamens. Some
consider this as one
stamen divided into
numerous antherine
cells by the connective.
... 555. Fruit of the Yew, a
naked seed partially
inclosed in a succulent receptacle.

cup-shaped receptacle (Fig. 555). They are natives of temperate regions, and abound in Asiatic countries.

Botany. are found also in Europe, New Zealand, and the Cape of Good Hope. Like the Conifers they yield valuable and durable timber, along with resinous and astringent matter. Some are poisonous. The seeds of Taxus baccata, the

common Yew, are narcotico-acrid.

Nat. Ord. 222.—GNETACEÆ, the Jointed-Fir order.— Small trees or creeping shrubs, not resinous, with jointed stems and branches, and opposite, reticulated, sometimes scaly leaves. They are closely allied to Coniferæ and Taxaceæ and are chiefly distinguished by the want of true cones, by the male flowers having a 1-leaved perianth, by the anthers being 1-celled and porose, by a third ovular covering next the nucleus being protruded through the foramen in a style-like manner, and by their long, twisted embryonic suspensor. The episperm is succulent. Natives of temperate as well as warm regions in Europe, Asia, and South America. The seeds of several of the species are eaten. Within the succulent episperm of Gnetum urens, stinging needle-like cells exist.
Nat. Ord. 223.—CYCADACEÆ, the Cycas order (Fig.

556).-Small palm-like trees or shrubs, with unbranched stems, occasionally dichotomous, marked with leaf-scars, and having large medullary rays, along with pitted tissue. Leaves pinnate, and usually circinate in vernation. Flowers 5 2 and achlamydeous. Males in cones, the scales bearing clusters of 1-celled anthers on their lower surface. Females consisting of ovules on the edge of altered leaves, or placed below or at the base of scales. Seeds either hard, or having a soft, spongy spermoderm, sometimes polyemCycas revoluta, one of the false Sago
plants found in Japan.

by a long suspensor in a cavity of fleshy or mealy albumen: cotyledons unequal. Natives chiefly of the tropical and temperate regions of America and Asia. Cycads have a mucilaginous juice, in which there is often much starch, which is used for food. Cycas revoluta (Fig. 556), a Japan species, has starchy matter in its stem, which is collected and eaten like Sago. C. circinalis,* in the Moluccas, yields a similar CXXXIV. kind of false Sago. Species of Encephalartos supply what is called Caffre-bread.

Note. - Among Thalamifloral Exogens, the following orders contain Monochlamydeous or Achlamydeous species:—Ranunculaceæ 1, Menispermaceæ 6, Papaveraceæ 13, Flacourtiaceæ 18, Caryophyllaceæ 28, Sterculiaceæ 31, Byttneriaceæ 32, Tiliaceæ 33, Malpighiaceæ 45, Geraniaceæ 54, Rutaceæ 63, Xanthoxylaces 64. Among Calycifloral Exogens, the following orders contain Monochlamydeous or Achlamydeous species:
—Celastraces 68, Rhamnaces 71, Amyridaces 73, Leguminoss 75, Rosaceæ sect. Sanguisorbeæ 77, Lythraceæ 79, Combretaceæ 82, Myrtaceæ 86, Halorageaceæ 91, Cucurbitaceæ 93, Passifloraceæ 96, Portulacaceæ 99, Illecebraceæ 100, Tetragoniaceæ 103, Saxifragaceæ 107, Cunoniaceæ 109, Loranthaceæ 115. Among Corollifloral Exogens, the following orders contain Monochlamydeous or Achlamydeous species:-Oleaceæ 140, Primulaceæ 168.

CLASS II.-MONOCOTYLEDONES, ENDOGENÆ, OR AMPHIBRYA,

SUB-CLASS I.—DICTYOGENÆ.

Endogens having Net-veined Leaves, which usually disarticulate with the Stem. Woody Matter of the Rhizome disposed in a circular wedge-like manner.

Nat. Ord. 224.—DIOSCOREACEÆ, the Yam order. Twining shrubs, with epigeal or hypogeal tubers, usually

alternate leaves, and small bracteated, unisexual flowers Botany. growing in spikes. Perianth 6-cleft, in 2 rows, herbaceous. adherent. Stamens 6, inserted into the base of the perianth. Ovary inferior, 3-celled; ovules 1-2, suspended; style trifid. Fruit compressed, 3-celled, 2 cells often abortive, sometimes fleshy. Seeds albuminous; embryo in a cavity. Chiefly found in tropical countries. Tamus grows in temperate regions. Acridity prevails in the order, but is often associated with a large amount of starch. Various species of Dioscorea, such as D. sativa, D. alata, and D. aculeata, produces edible tubers, which are known by the name of Yams, and are used like potatoes. Tamus communis, Black Bryony, has an acrid purgative and emetic root.

Nat. Ord. 225. SMILACEÆ, the Sarsaparilla order

(Fig. 557).—Herbs or shrubby plants, often climbing, with petiolate leaves jointed to the stem, and hermaphrodite or unisexual flowers. Perianth 6-parted. Stamens 6, perigynous or hypogynous. Ovary 3-celled; stigmas 3; ovules orthotropal. Fruit a few or many-seeded berry. Seed albuminous. Natives of temperate and tropical regions. The plants of the order have demulcent, mucilaginous, and diuretic properties. Smilax embraces the various species of Sarsaparilla, the roots of which are used medicinally as leaves which are jointed with the

cinalis supplies Jamaica Sarsaparilla, and according to Seemann, Lisbon or Brazilian, Guatemala, and Rio Paraguay Sarza.

Nat. Ord. 226.—TRILLIACEÆ, the Trillium order.—Herbs with tubers or rhizomes, verticillate leaves, and large terminal \$\forall flowers. Perianth of 6 or eight parts, in 2 rows, the inner sometimes coloured. Stamens 6, 8, or 10, with apicilar processes. Ovary superior, 3-5 celled; placenta axile; styles 3-5. Fruit succulent, 3-5-celled. Seeds ∞ , albuminous. Natives of the temperate parts of Europe, Asia, and North America. The properties of the order are acrid, narcotic, and emetic.

Nat. Ord. 227. - ROXBURGHIACEÆ, the Roxburghia order.—Twining shrubs, with large, solitary ♥ flowers, allied to Trilliaceæ, and distinguished chiefly by their 1-celled, 2-valved fruit, with a basal placenta. Perianth 4-leaved, coloured. Stamens 4, hypogynous. Ovules anatropal. Natives of the hot parts of India.

Nat. Ord. 228.—PHILESIACEÆ, the Philesia order.—A small order, nearly allied to the last, from which it differs in its trimerous symmetry, parietal placentas, and orthotropal ovules. The plants are found in Chili, and seem to have properties like Smilax.

SUB-CLASS II.—PETALOIDEÆ OR FLORIDÆ.

1.—Epigynæ.—Perianth adherent, Ovary inferior, Flowers usually Hermaphrodite.

Nat. Ord. 229.—Hydrochardaceæ, the Frog-bit order. -Aquatic plants, with spathaceous, 💆, or unisexual flowers. Perianth of 6 leaves, the three inner petaloid. Ovary 1celled, or spuriously 3-9-celled; stigmas 3-9; placentas parietal. Fruit dry or fleshy, indehiscent; seeds exalbuminous; embryo straight, orthotropal. This order ought probably to be placed among the unisexual plants, and close to Naiadaceæ. Its perianth, however, differs from that of the plants in the division Incompletæ. Found chiefly in

* Plate

Botany.

Botany. Europe, Asia, and North America. Movements in the cells are seen under the microscope (Fig. 23). Anacharis Alsinastrum has become naturalized in many parts of Britain, and grows so rapidly as to fill up water-courses. Vallisneria (Fig. 22) is remarkable for its mode of impregnation.

Nat. Ord. 230.—Orchidaceze, the Orchis order (Figs. 558 and 559).—Terrestrial or epiphytic herbs or shrubs,

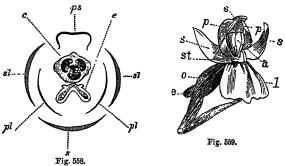

Fig. 558. Diagram of the flower of Orchis, s, sl, sl, the three divisions of the outer perianth, the first being inferior and the other two lateral; pl pl, the two lateral divisions of the inner perianth, ps, the superior division or the labellum, which becomes inferior by the twisting of the ovary; c, the fertile stamen, with its two pollen masses in the anther-lobes, the two lateral stamens are abortive; s, the one-celled ovary out transversely, having three parietal placentas.

centas.

559. Flower of an Orchid, consisting of three outer divisions of the perianth, s s, three inner p p l, the latter l, being the labellum, which is inferior in this figure by the twisting of the ovary; s, the spur of the labellum; o, the twisted ovary; s, the stigma; a, the anther containing pollinia.

with fibrous or tuberous roots (Fig. 69), a short stem or a pseudo-bulb (Fig. 70), entire, often sheathing leaves, and hermaphrodite showy flowers. Perianth of 6 segments, in two rows, mostly coloured, one, the lowest (so situated from the twisting of the ovary) generally differing in form from the rest, and often spurred; it is called the labellum or lip, and has sometimes 3 marked portions,—the lowest being the hypochilium, the middle the mesochilium, and the upper the epichilium. By adhesion or abortion, the parts of the perianth are sometimes reduced to 5 or 3. Essential organs united on a common column or gynostemium. Stamens 3, the 2 outer, sometimes the central one, being abortive; anthers 2-4-8-celled; pollen powdery, or adhering in masses called pollinia (Fig. 265), attached to the rostellum by a naked or saccate gland. Ovary 1-celled, with 3 parietal placentas, stigma a viscid space in front of the column. Fruit usually a 3-valved capsule, which often opens by 6 portions, owing to the midribs of the valves separating. Seeds ∞ , exalbuminous, with a loose reticulated episperm; embryo solid and fleshy. This order is well distinguished by its peculiar gynandrous flowers, labellum, and pollinia. Fragrant, aromatic, tonic, and mucilaginous properties are met with among Orchids. The roots of some of the terrestrial species contain much bassorin, and they constitute the nutritious substance called Salep. Blue colouring matter, like indigo, is met with in the leaves and flowers of some species. Orchis mascula, and other species, such as O. Morio and O. papilionacea, yield Salep. Vanilla planifolia and aromatica yield the fragrant Vanilla, used in confectionary and in the preparation of Chocolate.

Nat. Ord. 231.—Apostasiaceæ, the Apostasia order. -A small order of herbaceous plants closely allied to Orchids, from which they differ chiefly in their regular flowers, 3-celled loculicidal fruit, and in the style being free from the stamens throughout a considerable part of its length. The column is short, and is formed by the filaments along with the lower part of the style. Natives of the hot forests of India.

Nat. Ord. 232.—BURMANNIACEÆ, the Burmannia order. -A small order of herbaceous plants, with tufted, radical, acute leaves, or none, and a slender stem bearing alternate bract-like leaflets. They resemble Orchids in their minute

seeds with a loose reticulated episperm, their parietal placentas, and their solid embryo; and are chiefly distinguished by their regular tubular flowers, stamens 3 or 6, dehiscing transversely, free, and inserted into the tube of the coloured perianth. Natives chiefly of tropical regions in Asia, Africa, and America.

Nat. Ord. 233.—ZINGIBERACEÆ or SCITAMINEÆ, the Ginger order (Fig. 560).—Herbs, with a rhizome, simple sheathing leaves, the veins parallel and diverging from a midrib, and flowers arising from membranous spathes. Perianth tubular, irregular, and in 3 rows, the outer (calyx) 3-lobed, the middle (corolla) and inner (staminodes) each 3-parted, with a segment differing from the rest-Stamens 3, free, the two lateral abortive; anthers 2-celled. Fruit a 3-celled capsule or berry. Seeds numerous, albuminous; embryo in a vitellus. Nearly all tropical plants; abundant in the East Indies. plants of this order have aromatic, stimu- Zingiber officinale, lating properties, and are used as condiments, and as stomachic remedies. * Their or rootstock and spathaceous flowers are often very gaudy, and their bracts flowers.

Fig. 560.

are sometimes finely coloured. The capsules of Amomum Cardamomum are called round Cardamoms; those of A. angustifolium are the Madagascar Cardamoms. Curcuma longa has a yellow coloured rhizome, the branches of which constitute Turmeric. Zingiber officinale (Fig. 560) has an aromatic rhizome which constitutes Ginger.

Nat. Ord. 234.-MARANTACEÆ or CANNACEÆ, the Arrow-root order.-Herbaceous plants closely allied to Zingiberaceæ, from which they differ chiefly in the want of aroma, in having one of the lateral stamens fertile (the other two being abortive), in the single stamen having a petaloid filament, which bears a 1-celled anther (the other antherine lobe being sterile), in the style being petaloid, and in the embryo not being contained in a vitellus (Fig. 420). Natives of the tropics of America, Africa, and Asia. Amylaceous qualities prevail in this order, and starch is prepared from many of the species. The corms or rhizomes of Canna coccinea, C. edulis, and C. Achiras, all yield starch, some of which is known as Tous-les-mois. Maranta arundinacea yields Arrow-root.

Nat. Ord. 235.—MUSACEÆ, the Banana order (Fig. 561).

-Plants with underground stems, their petioles forming a spurious aerial stem (Fig. 86), their leaves having parallel veins diverging from a midrib, and their flowers being bracteated. Perianth irregular and petaloid, 6-parted in 2 rows. Stamens 6, inserted on the perianth. Anthers linear, 2-celled, often crested. Fruit a 3-celled loculicidal capsule, or succulent and indehiscent (Fig. 561). Seeds albuminous; embryo orthotropal. Tropical plants, which are valuable as regards food, clothing, and other domestic fruit of the Banana.

Durposes. They yield much nutritive (Musa sapientum). They yield much nutritive purposes.

Fig. 561.

food, as well as useful fibres. Musa paradisiaca, the Plantain, and M. sapientum, the Banana, supply well-known fruits, which serve for the food of the inhabitants of many tropical countries. M. textilis produces Manilla Hemp, which is used in manufacture.

Nat. Ord. 236.—IRIDACEÆ, the Iris order (Figs. 562 and 563).—Herbs with corms, rhizomes, or fibrous roots, and mostly equitant leaves, and spathaceous flowers. Perianth 6-divided in 2 rows, sometimes irregular. Stamens 3, inserted at the base of the outer row of the perianth; anthers innate, extrorse. Style dividing into 3 petaloid stigmatiferous portions (Fig. 563). Capsule 3-celled, 3-valved,

Found in various Botany. loculicidal. Seeds with hard albumen. temperate and warm parts of the world. The order has its maximum at the Cape of Good Hope. Acrid, purgative, and emetic properties are met with in some plants of the

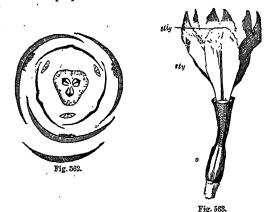

Fig. 562. Diagram of the flower of Iris, showing a bract or spathe below, three outer divisions of the persanth with hairs, three inner, three stamens, and three divisions of the ovary.

... 563. Fower of Iris, with the limb of the persanth removed. The ovary o, tube of persanth, t, upper petaloid and divided part of the style, stylen, stylen, stylen. sty, stigma, stig.

Some are fragrant and aromatic; others supply starch and materials for dyeing. The dried stigmatic processes of Crocus sativus constitute Saffron. The rhizome of Iris florentina, the Florence Iris, is the aromatic Orrisroot, which has the odour of Violets.

Nat. Ord. 237.—AMARYLLIDACEÆ, the Amaryllis order

(Fig. 564).—Bulbous, sometimes fibrous-rooted plants, with ensiform leaves, and showy flowers, which are mostly spathaceous and on scapes (Fig. 149). Perianth coloured, limb 6-parted or 6-cleft, sometimes with a corona, as in Narcissus (Fig. 149). Stamens 6, inserted at the bottom of the segments, sometimes united by a membrane, as in Pancratium; anthers introrse. Stigma 3-lobed. Fruit a 3-celled, Diagram of the flower of Leuco-3-valved, loculicidal capsule, with many seeds; or a berry with 1-3 seeds, spermoderm not crustaceous; albumen fleshy; embryo

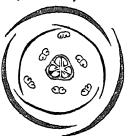

Fig. 564.

olagram of the nower of Leuco-jum versum, Spring Snowflake, with six divisions of the pe-rianth, three outer and three inner, six stamens in two ver-ticits, and a three-celled overy with a contral placents.

with radicle next the hilum. Natives of various parts of the world, but attaining their maximum at the Cape of Good Hope. Many Amaryllids display poisonous properties. Some are emetic and purgative, and some yield useful fibres. The bulbs of the Snowdrop and Snowflake are said to be emetic. Agave americana, American Aloe, is used in America for the manufacture of an intoxicating beverage. Its fibres constitute Pita Flax, and are sometimes made into paper.

Nat. Ord. 238.—HYPOXIDACEÆ, the Hypoxis order.— Herbs, with tuberous or fibrous roots, linear, dry, often hairy leaves, and trimerous flowers in scapes. Closely allied to Amaryllids, and differing chiefly in their strophiolate seeds, and embryo with the radicle remote from the hilum. Natives of warm regions.

Nat. Ord. 239.—Hemodoraceæ, the Blood-root order. -Perennial plants, with fibrous roots, ensiform equitant leaves, and woolly hairs or scurf on their stems and flowers. Perianth tubular, 6-divided. Stamens 3, opposite the segments, or 6; anthers introrse. Ovary 3-celled, sometimes 1-celled; style and stigma simple. Fruit usually capsular and valvular, covered by the withered perianth. Embryo

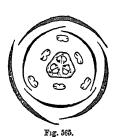

in cartilaginous albumen, radicle remote from the hilum. Botany. Natives of America, the Cape, and New Holland. Bitterness is found in some of the plants of the order (Aletris). Their roots are sometimes nutritious, and many of them are of a red colour, whence the name of the order.

Nat. Ord. 240.—TACCACEÆ, the Tacca order.—Perennial herbs, with tuberous roots, radical curve-veined leaves, and flowers in scapes. Perianth tubular, 6-divided. Stamens 6, inserted in the base of the segments; filaments petaloid; anther below the points of the filaments. Styles 3. Fruit baccate, 1-celled, or half 3-celled. Albumen fleshy. Acrid plants found in the warmest parts of India and Africa, as well as in the South Sea Islands. The tubers of Tacca pinnatifida, and other species, yield starch.

Nat. Ord. 241.—Bromeliace , the Pine-apple order.— American and chiefly tropical plants, with rigid, channelled, often scurfy and spiny leaves, and showy flowers. Outer perianth 3-parted, persistent; inner of 3 withering leaves. Stamens 6, inserted in the tube of the perianth; anthers introrse. Style single. Fruit capsular or succulent, 3-celled, many-seeded. Embryo minute, in the base of mealy albumen. Many of the plants grow in an epiphytic manner, and are called air-plants. This is the case especially with Tillandsias. Some of the species have anthelmintic properties. Some supply edible fruit, gum, colouring matter, and valuable fibres. The fibres of Ananassa sativa, the Pine-apple, are used in manufacture.

2. Hypogynæ.—Perianth free, Ovary superior, Flowers usually Hermaphrodite.

Nat. Ord. 242.—LILIACEÆ, the Lily order (Figs. 565 and 566).—Herbs, shrubs, or trees, with bulbs (Fig. 111),

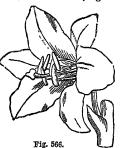

Fig. 565. Diagram of the flower of Fritillaria imperialis, Crown Imperial, showing a perianth of 6 parts, in two verticils, 6 stamens in two rows, and a 3-celled ovary.

... 566. Flower of Lilium album, White Lily, with a 6-leaved perianth, 6 stamens, and 1 style.

corms, rhizomes (Fig. 73), or fibrous roots, simple, sheathing, or clasping leaves, and regular flowers. Perianth coloured, of 6 leaves (Fig 566), or 6-cleft. Stamens 6, inserted in the perianth; anthers introrse. Ovary_3-celled (Fig. 279); style 1; stigma simple or 3-lobed. Fruit trilocular, capsular, or succulent. Seeds in 1 or 2 rows, sometimes in pairs or solitary; albumen fleshy. Natives both of temperate and tropical regions. In the latter we meet with arborescent species, such as the Dragon-trees, and with succulent species, as Aloes. In temperate climes we have species of Tulip, Lily, Hemerocallis, Convallaria, Fritillary, Hyacinth, and Star of Bethlehem. The properties of the order are various. Some of the plants are used as emetics and purgatives, while others are stimulant and diaphoretic. Some yield resinous and astringent matter, while others supply valuable materials for manufactures. Aloe is the genus which supplies the drug called Aloes. It is the inspissated juice of various species, such as A. spicata, vulgaris, socotrina, indica, and purpurascens. Phormium tenax supplies New Zealand flax. Urginea Scilla, known as Scilla or Squilla maritima, a Mediterranean sand plant, has an acrid bulb which, when dried.

Fig. 567.

Botany. constitutes the common Squill of the shops. It is used as an emetic, expectorant, and diuretic.

Nat. Ord. 243.—MELANTHACEÆ or COLCHICACEÆ, the Colchicum order (Fig. 567).—Herbs, with bulbs, corms (Fig. 74), or fasciculated roots, and white, green, or purple flowers, which are sometimes polygamous. Perianth petaloid, of 6 leaves, which are either separate, or united below into a tube. Stamens 6, anthers extrorse. Ovary 3-celled; style 3-parted; capsule 3-valved, septicidal (Colchicum), sometimes loculicidal (Uvularia). Seeds with a membranous episperm, and dense, fleshy albumen. Generally distributed over the world, but most abundant in northern countries. The

Diagram of the flower of Colchicum autumnale, Meadow Saffron, showing a 6-leaved perianth, in 2 verticils, 6 stamens, and an ovary formed of 3 car-pels. plants of this order have acrid, emetic, purgative, and sometimes narcotic properties. They are all more or less poisonous, and nearly all seem to contain the alkaloid called Veratria. Asagræa officinalis, is the chief source of the Cevadilla or Sabadilla seeds, which contain veratria, and are used in neuralgic and rheumatic affections. The corms and ripe seeds of Colchicum autumnale, the Meadow Saffron, contain an alkaloid Colchicia, and are prescribed in gout and rheumatism.

Nat. Ord. 244.—GILLIESIACEÆ, the Gilliesia order.—Bulbous herbs, with grass-like leaves, and umbellate, spathaceous flowers. Perianth of 2 portions,—outer petaloid and herbaceous, of 6 leaves, called by Lindley bracts; inner minute, either a single lobe or urceolate and 5-toothed. The latter is by some considered an abortive staminal row. Stamens 6, sometimes 3 sterile. Capsule 3-celled, 3-valved, loculicidal, polyspermal. Episperm black and brittle; embryo curved; albumen fleshy. Chilian plants.

Nat. Ord. 245.—Pontederia ce.e., the Pontederia order.-Aquatic plants, with leaves sheathing at the base, petioles occasionally dilated, and spathaceous flowers, either solitary or in spikes. Perianth coloured, tubular, 6-parted, irregular, persistent. Stamens 6 or 3, perigynous; anthers introrse. Capsule sometimes slightly adherent, 3-celled, 3-valved, loculicidal. Seeds numerous; placenta central; albumen mealy. Natives of America, India, and Africa.

Nat. Ord. 246.—XYRIDACEÆ, the Xyris order.—Swampy rush-like plants, with ensiform or filiform radical leaves sheathing at the base. Flowers in scaly heads. Perianth of 6 parts, 3 outer glumaceous. Stamens 6, 3 fertile inserted on the inner perianth. Anthers extrorse. Ovary 1celled; placentas parietal; ovules orthotropal. Capsule 1celled, 3-valved, polyspermal. Albumen fleshy; embryo remote from the hilum. Tropical plants. Some species of Xyris have been used in cutaneous affections.

Nat. Ord. 247.—PHILYDRACEÆ, the Water-wort order. -Plants allied closely to Xyrids, and differing chiefly in the want of an outer perianth, in the inner perianth being 2leaved, in having 3 stamens, 2 of which are abortive, and in the embryo being large in the axis of the albumen. The flowers have spathaceous bracts; the roots are fibrous, the stem simple, leafy, and often woolly, and the leaves sheath-

ing at the base. Natives of New Helland and China. Nat. Ord. 248.—COMMELYNACEÆ, the Spider-wort order. -Herbs, with flat leaves, usually sheathing at the base. Outer perianth of 3 parts, herbaceous; inner also 3, coloured, sometimes cohering. Stamens 6, or fewer, hypogynous. Anthers introrse; ovary 3-celled; placenta central; style 1. Capsule 2-3-celled, 2-3-valved, loculicidal. Seeds with a linear hilum; embryo pulley-shaped, in a cavity of the albumen, remote from the hilum. In Tradescantia the filaments are provided with jointed hairs, which show rotation in their cells. The rhizomes of some species of Commelyna are amylaceous and edible.

Nat. Ord. 249.—MAYACACEÆ, the Mayaca order.—Moss- Botany. like plants, with narrow leaves, resembling Spider-worts, but differing in their 1-celled anthers, carpels opposite the inner divisions of the perianth, 1-celled ovary and capsule, and parietal placentas. Natives of America.

Nat. Ord. 250.—Juncaceæ, the Rush order (Figs. 568 and 569).—Herbs, with fasciculate or fibrous roots, fistular or

Fig. 569. Fig. 563. Diagram of the flower of Luzula, Wood-rush, showing 6 divisions of the perianth in 2 rows, 6 stamens, and a 3-celled ovary.

... 569. Perianth of Luzula, with 6 divisions of its glumaceous perianth, 6 stamens, pistil with 1 style and 3 stigmas.

flat and grooved leaves, and glumaceous sometimes petaloid flowers in clusters, cymes, or heads. Perianth dry, greenish or brownish, 6-parted (Fig. 569). Stamens 6 or 3, perigvnous; anthers introrse. Ovary 1 or 3-celled; ovules 1, 3, or many in each cell; style 1; stigmas often 3. Fruit a 3-valved loculicidal capsule, or monospermal and indehiscent. Seeds with a thin spermoderm, which often becomes gelatinous when moistened; albumen fleshy; embryo minute. Natives chiefly of cold and temperate regions. The leaves are used to form matting and the bottoms of chairs, and the pith for the wicks of candles.

Nat. Ord. 251.—Palmæ, the Palm order (Fig. 570 to 573).—Arborescent plants, with a simple (Fig. 570), some-

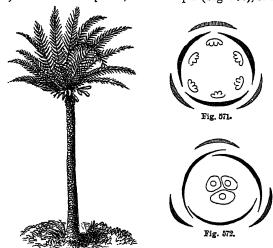

Fig. 570. Fig. 570. Phœnix dactylifera, the Date Palm. ... 571. Diagram of the 5 flower of Chamærops, Fan-palm, showing six divi-sions of the perianth and six stamens. "... 572. Diagram of the Q flower of Chamærops, showing six divisions of the perianth in two rows, and three cells of the ovary.

times branched stem, marked by the bases of the leaves or

their scars, leaves in terminal clusters, pinnate or fan-shaped flowers 5 ♀ or Ş, on a simple or branched spadix, inclosed in a 1 or many-valved spathe. Perianth in two verticils, each of 3 parts (Figs. 571 and 572). Stamens usually 6, seldom 3, sometimes ∞. Ovary 1-3-celled, with a single ovule in each cell. Fruit a nut or drupe, or berry. Albumen cartilaginous or hard, often ruminate,

Botany. with a central cavity; embryo in a particular cavity remote from the hilum (Fig. 573), its cotyledon often becoming enlarged during germination, and filling the central cavity. Chiefly tropical plants, requiring a mean temperature of 78°2 to 81°.5 F. Some, however, extend to temperate regions. Chamærops humilis, the dwarf Fan-palm, is found native in the south of Europe, and C. Palmetto grows in the milder parts of North America. Some have slender, reed-like stems, others attain a considerable diameter. Some have a low caudex, or a subterranean stem, while others have an erect trunk 190 feet high. Palms yield numerous important products, and they are applied to a great many uses. They supply starch, sugar, oil, wax, and edible fruits; their buds are eaten like vegetables; their leaves form coverings for habitations, and materials for manuscripts, the reticulum makes coarse cloth, and the saccharine juice is sometimes fermented, so as to form a spirit called arrack, or palm-wine called toddy. Areca Catechu furnishes the Betel-nut, used all over the East as a masticatory. Cocos nucifera, the Coconut Palm is perhaps put to a greater number of uses than any other Palm, both as regards food, luxuries, clothing, habitations, and utensils. Elais guineensis supplies the solid Palm-oil. Metroxylon læve, a native of Borneo and Sumatra, is one of the sources of the starchy matter called Sago. Phytelphas macrocarpa, a Palm of the Magdalena River district, is called the Vegetable Ivory-Palm, because the hard horny albumen of its seed is used like ivory. Sagus Rumphii is the Sago-Palm of Malacca.

Nat. Ord. 252.—Alismaceæ, the Water-plantain order. -Floating or marsh plants, with a creeping rhizome, narrow or broad leaves, and flowers in umbels, racemes, or panicles. Perianth of 6 pieces; outer 3 herbaceous; inner 3 petaloid. Ovaries several, 1-celled; ovules solitary, or 2 superposed. Fruit indehiscent. Seeds exalbuminous; embryo like a horse-shoe, undivided. Natives chiefly of northern countries. The fleshy rhizomes of Alisma and Sagittaria are edible.

Nat. Ord. 253.—Juncaginaceæ, the Arrow-grass order. -Marsh plants, with narrow radical leaves, and ♥ flowers in spikes or racemes. Perianth greenish. Stamens 6; anthers extrorse. Carpels 3-6, united, or distinct; ovules 1 or 2, erect. Fruit dry, 1-2-seeded. Albumen 0; embryo straight, with a lateral cleft. A small order of plants found in cold and temperate regions.

Nat. Ord. 254.—BUTOMACEÆ, the Flowering-rush order. -Aquatics, with very cellular leaves, often milky, and umbellate handsome flowers. Perianth of 6 pieces, 3 inner petaloid. Stamens definite or ∞ . Ovaries 3-6 or more, distinct or united; ovules ∞ . Fruit, follicles, distinct or united. Seeds ∞ , attached to a reticulated placenta, spread over the whole inner surface of the fruit; albumen 0. Natives chiefly of northern countries.

3. Incomplete.—Flowers incomplete, generally Unisexual, without a proper Perianth, or with a few Verticillate

Nat. Ord. 255.—Pandanaceæ, the Screw-pine order.— Trees or bushes, often branching dichotomously, or in a candelabra-like manner, having adventitious roots (Fig. 66), leaves imbricated, linear-lanceolate or pinnate or fan-shaped, and spiny; and flowers unisexual or polygamous, spathaceous, covering a spadix completely. Perianth 0, or a few scales. Stamens numerous; anthers 2-4-celled. Ovaries 1-celled, collected into parcels; stigmas sessile; ovules solitary or numerous. Fruit either 1-seeded fibrous nuts, or manyseeded berries. Albumen fleshy; embryo minute, without a lateral slit. Natives of tropical regions, and abundant in insular situations.

Nat. Ord. 256.—TYPHACEÆ, the Bulrush order.—Herbs, growing in marshes or ditches, having stems without nodes, igid, ensiform leaves, and monœcious flowers on a spadix, without a spathe. Perianth 3 or more scales, or a bundle Botany. of hairs. Stamens 1-6, distinct or monadelphous; anthers innate. Ovary solitary, 1-celled; ovule solitary, pendulous. Fruit dry or spongy, indehiscent, 1-celled, angular by pressure. Seed solitary, pendulous, with a membranous sper-moderm adhering to the pericarp. Embryo in the axis of mealy albumen, straight with a lateral cleft; radicle next the hilum. Most abundant in northern countries. Starch is a product of the rhizomes of many species of Typha, and the pollen, which is very abundant, is inflammable, and is also used for food.

Nat. Ord. 257.—Araceæ, the Arum order.*—Herbs or *Plate shrubby plants, sometimes climbing, often with corms; leaves CXXXV sheathing at the base, convolute in æstivation, sometimes compound, and usually with branching veins; flowers monœcious, on a spadix (Fig. 166), mostly with a spathe. Perianth 0. Stamens definite or on; anthers extrorse, 1 or 2-celled or more. Ovary with 1 or more cells. Fruit succulent; seeds pulpy; embryo in the axis of fleshy and mealy albumen, with a lateral cleft. Abundant in tropical climates; rare in cold or temperate regions. Acridity prevails in the order, and many of the plants are irritant poisons. The corms sometimes supply starch, which is separated from the acrid matter by washing. Arum maculatum, Cuckow-pint, or Wake-Robin, has an amylaceous acrid corm. The starch used to be separated in large quantities at Weymouth and in the island of Portland, and sold under the name of Portland Sago. Colocasia esculenta, and other species, have edible corms, which are called Cocoes and Eddoes in the West Indies.

Nat. Ord. 258.—Orontiaceæ or Acoraceæ, the Orontium or Sweet-flag order.-Herbs with broad, occasionally ensiform leaves, and spadiceous flowers inclosed by a spathe. They are usually associated with Araceæ, from which they differ in their hermaphrodite flowers, and in having frequently a perianth consisting of 4-8 scales. Lindley, on account of their & flowers, places them near Juncaceæ. Natives both of tropical and cold regions. Acridity is met with in this order, which also contains nutritious, bitter, and aromatic plants. Acorus Calamus, common Sweet-Sedge, has an agreeable odour, and has been used as a stimulant, tonic, and antispasmodic. Its starchy matter is associated with a fragrant oil, and is used as hair-powder.

Nat. Ord. 259.—Pistiaceæ or Lemnaceæ, the Duck-

weed order (Fig. 574).—Floating plants with lenticular or lobed leaves or fronds, bearing 1 or 2 monœcious flowers inclosed in a spathe, but with no perianth. Stamens definite, often monadelphous. Ovary 1celled; ovules 1 or more, erect or horizontal. Fruit indehiscent or membranous, or bursting transversely, or baccate, I or more-seeded. Seeds with a thick ribbed episperm and an indurated micropyle; embryo in the axis of fleshy albumen, with a lateral cleft, or at the apex of the nucleus. Natives both of cool and of warm regions. Lemnas form a green covering of pools in Britain. Pistia Stratiotes, Water - lettuce,

floats in the ponds of warm countries.

Nat. Ord. 260.—NAIADACEÆ or POTAMOGETONACEÆ, the Naias or Lemna minor, lesser Duckweed, showing the imperfect flowers produced on the frond and the distinct pictorhize or sheaths, 7, at the extremities of the roots.

Fig. 574.

Pondweed order.—Plants of fresh or salt water, with cellular leaves and stems, and inconspicuous spiked flowers, which are sometimes hermaphrodite. Perianth of 1-4 scaly pieces or 0. Stamens definite, hypogynous. Ovary free, of one or more carpels, 1-celled; ovule solitary, erect or

Botany. pendulous, rarely 3 and erect. Style simple, or 2-3-cleft. Fruit indehiscent, dry, 1-celled, and usually 1-seeded; albumen 0; embryo with a lateral cleft. What is called the perianth in Potamogeton, and a few other allied genera, is considered by some as composed of bracts, bearing unisexual flowers. If that is the true view, then this order will not include any plants. Natives of temperate and warm climates. Some species are styptic, others yield edible roots, and a few, as Zostera, are used for stuffing cushions and beds.

Nat. Ord. 261.—Triuridaceæ, the Triuris order.—A small tropical order of cellular, unisexual plants, allied to Naiadaceæ, but distinguished in part by their peculiar seed, which consists of a hard striated integument, containing an embryo in the form of a multicellular nucleus.

Nat. Ord. 262.—RESTIACEÆ, the Restio order.—Herbs or undershrubs, with narrow leaves or 0, naked or sheathed stalks, and flowers in bracteated heads or spikes, generally δ ♀; glumaceous bracts 2-6, sometimes 0. Stamens 2-3; anthers usually 1-celled. Ovary 1 or more-celled; ovules, one in each cell, pendulous. Fruit a capsule or nut. Embryo lenticular, outside the albumen. Natives chiefly of South America, Australia, and South Africa. Their wiry stems are used for baskets and brooms, and for thatching.

Nat. Ord. 263.—Eriocaulonaceæ, the Pipewort order. -Marsh plants, with minute, unisexual flowers, allied to the last order, and differing principally in their capitate inflorescence, 2-celled anthers, ovary surrounded by a 2-3toothed membranous tube, and seeds with rows of hairs. The species abound in South America, and they are also found in Australia and North America. Eriocaulon septangulare, jointed Pipewort, is the only species found in Britain. It is met with in Skye and Galway.

Nat. Ord. 264.—Desvauxiaceæ, the Bristlewort order. -Small herbs, like species of Scirpus, having setaceous leaves, flowers glumaceous in a spathe, distinguished from Restiaceæ principally in having separate ovaries attached to a common axis, and fruit consisting of utricles opening longitudinally. They inhabit the South Sea Islands and New Holland.

SUB-CLASS III .-- GLUMIFERÆ.

Nat. Ord. 265.—CYPERACEÆ, the Sedge order (Figs. 575 to 577).—Grass-like, cæspitose plants, have solid, usually unjointed, and frequently angular stems, leaves with en-

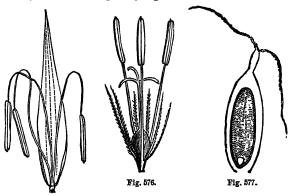

Fig. 575. Fig. 575. Staminiferous flower of Carex, consisting of a scale or glume bearing
3 stamens with long filaments and innate anthers.
... 576. Hermaphrodite flower of Scirpus, Club-rush. The glume has been
removed, and there are seen six hypogynous, retrorsely-toothed
bristles, three stamens with innate anthers, and the pistil with a
single style and three stigmas.
... 577. The ripe pistil of Carex cut vertically, showing the minute embryo
in the base of the albumen.

tire sheaths, and \(\rightarrow \rightarr or glume (Fig. 575), imbricated on a common axis, so as to form a spikelet. The lowermost glumes are often empty. Perianth 0, or existing in the female flowers in the form of

a membranaceous covering called perigynium (Fig. 235). Botany. Stamens hypogynous, definite, varying from 1 to 12, most commonly 3; anthers innate, 2-celled. Ovary superior, often surrounded by hypogynous bristles called setæ (Fig. 576); ovule 1, erect; style single, 2-3-cleft; stigmas 2-3. Fruit a crustaceous or bony achene. Embryo lenticular, in the base of fleshy or mealy albumen (Fig. 577). Generally distributed all over the world, and growing abundantly in moist situations. Some of the Sedges are diaphoretic and demulcent, others are bitter, stomachic, and astringent. The creeping stems of Carex arenaria are used as a substitute for Sarsaparilla.

Nat. Ord. 266.—Gramineæ, the Grass order (Figs. 578 and 579).—Herbaceous plants, with round, usually hollow,

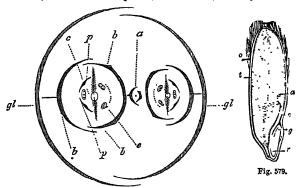

Fig. 578. Fig. 578.

Fig. 578.

Diagram of a spikelet of Avens, Oat, showing two glumes, gl gl, inclosing three flowers, one of which, a, is abortive; the two pales or glumeles, b b the inner apparently formed by the union of two; two scales, lodicules, p p, the third being abortive and marked by a dotted curve; three stamens, e, ovary, c, with two feathery styles.

279. Caryopsis, grain of Oat; pericarp, o, spermoderm, t, farinaceous albumen, a. Embryo plant lying at one side at the base, with radicle, r, plumule, g, and cotyledon, c.

jointed stems; narrow, alternate leaves, having a split sheath and often a ligule at its summit (Fig. 134); hermaphrodite or monœcious, or polygamous flowers, either solitary or arranged in spiked or panicled locustæ (Fig. 165). The flowers are considered as composed of a series of bracts; the outer, called glumes (Figs. 150 and 231), alternate, often unequal, usually 2, sometimes 1, rarely 0; the next, called pales or glumelles (paleæ or glumellæ), usually 2, alternate (Figs. 232 and 233), the lower or outer one being simple, the upper or inner having 2 dorsal or lateral ribs, and supposed to be formed by 2 pales united; sometimes 1 or both are wanting. The glumes inclose either one flower, as in Fox-tail grass, or more flowers, as in Wheat (Fig. 165), and among the flowers there are frequently abortive florets (Fig. 150). Stamens hypogynous, 1-6, usually 3 (Fig. 234); anthers versatile. Ovary superior, 1-celled, with 2 (rarely 1 or 0) hypogynous scales called lodicules (Figs. 234, sq); ovule 1; styles 2 or 3, rarely united; stigmas often feathery (Fig. 234). Fruit a caryopsis. Embryo lenticular, external, lying on one side, at the base of farinaceous albumen (Fig. 579). Germination endorhizal (Fig. 419). Grasses are widely distributed, and are found in all quarters of the globe. Schouw conjectures that they constitute 1-22d of all known plants. They are usually social plants, forming herbage in temperate regions, and sometimes becoming arborescent (50 or 60 feet high) in tropical countries. is perhaps the most important order in the vegetable kingdom, as supplying food for man and animals. To it belong the cultivated grains, Wheat, Oats, Barley, Rye,* Rice, *Plate Maize, and Millet. Most of these have been so long under CXXXVIL constant cultivation that their native state is unknown. The

properties of the order are nutritive in a marked degree.

Some yield fragrant oils, others produce sugar. The fra-

grant odour given out by Anthoxanthum, and other grasses used for hay, has been attributed to benzoic acid. Lolium

Botany. temulentum, Darnel-grass, has been said to be narcotic and poisonous, but this has not been fully proved. Andropogon Schananthus, Lemon-grass, and A. Calamus aromaticus, yield a fragrant oil. Bambusa arundinacea, the Bamboo, attains a great height, and in hothouses in Britain it has sometimes grown at the rate of a foot or more per day. Saccharum officinarum, is the Sugar-cane.

II.—CRYPTOGAMEÆ, ACOTYLEDONEÆ, OR FLOWERLESS PLANTS.

CLASS III.-ACOTYLEDONES OR ACRO-THALLOGENÆ. SUB-CLASS I.—ACROGENÆ, ACROBRYA, OR CORMOGENÆ.1

Nat. Ord. 267.—FILICES, the Fern order (Figs. 580 to 582).—Leafy plants, the leaves, or more properly fronds, being circinate in vernation (Fig. 100), and arising from a rhizome (Fig. 580), or from a hollow arborescent trunk (Fig. 87), having the acrogenous structure. The fronds bear on the veins of their lower surface (Figs 580 and 581), or along

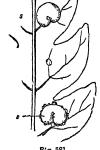

Fig. 580. Fig. 581. Fig. 580.

Fig. 580. Short-fruited Spleenwort or Lady-fern (Athyrium Filia-formina).

1. The entire fern with its short rhizome, and its delicate fronds, which, in the young state, are rolled up in a circinate manner;

2, one of the pinne, with its pinneles, bearing the oblong slightly-entired sori (clusters of sporangia) on their back. The fern is dorsiferous.

581. Portion of the frond of the male Shield-fern (Lastrea Felia-mas), showing two sori, 2 s, or clusters of sporangia covered with a reniform involucre or industum attached by the sinus.

their margins, sporangia, which open in various ways in order to discharge minute spores. The supposed organs of reproduction, called antheridia and archegonia (Figs. 396 and 398) are seen on the young frond, when first developed from the spore in the form of a prothallus.

The following divisions have been adopted:-Suborder 1. Polypodiaceæ, the Polypody tribe (Fig. 580); Sporangia, in variously-shaped clusters, called sori, on the back

or margins of the fronds, each sporangium having a vertical, incomplete ring (annulus), or a horizontal complete one, which, when mature, straightens so as to open the spore-case transversely, or irregularly, and thus discharge the spores (Fig. 354). The sori are covered by an indusium or involucre (Fig. 581), or by the reflexed margins of the frond.—Sub-order 2. Osmundaceæ, the Flowering-fern tribe (Fig. 582); Sporangia dorsal, or clustered on the margin of a transformed frond, with a terminal or dorsal ring, more or less complete, reticulated, and opening vertically.—Sub-order 3. Ophioglossaceæ, the Adder'stongue tribe; Sporangia in a

Fig. 582. Fig. 587.
Frond of the Royal Fern (Osmunda regalis), bearing divided pinne. f. The frond is bipinnate. At the extremity of the frond the pinne are altered so as to bear fructification, consisting of sporangia, arranged in a spikelike manner on a number of short axes.

spike-like form, sessile on the margin of a contracted frond, Botany. without reticulation or a ring (exannulate), 2-valved; fronds with straight vernation.—Sub-order 4. Danæaceæ, the Danæa tribe; Sporangia dorsal, combined in masses, exannulate, splitting irregularly by a central cleft. A moist insular climate is that best adapted for ferns in general. Ferns characterize the flora of New Zealand. Some Ferns are used medicinally as anthelmintics, while others are demulcent and astringent. The rhizomes of several species, are used as food in Australia, the Sandwich Islands, and India. Adiantum Capillus Veneris, true Maiden-hair, has been used in the preparation of Syrup of Capillaire. Lastrea Filix-mas is an effectual vermifuge in cases of Tape-worm.

Nat. Ord. 268.—Marsileaceæ or Rhizocarpeæ, the Pepperwort or Rhizocarp order.—Aquatic plants, with creeping stems, bearing leaves, which are usually divided into 3 or more cuneate portions, and have a circinate vernation. The fructification is produced at the base of the leafstalks, and consists of sporocarps or involucres inclosing clustered organs (Fig. 360), which consist of antheridian and pistillidian cells. The germinating body has an oval form, and occasionally a mammilla on one side, whence roots and leaves proceed. Found in ditches in various parts of the

world, chiefly in temperate regions.

Nat. Ord. 269.—LYCOPODIACEÆ, the Club-moss order.— Plants with creeping stems or corms, which produce leafy branches (Fig. 357), somewhat resembling Mosses. The leaves are small, sessile, and imbricated or verticillate. The fructification occurs in the axil of leaves, and often in a spike-like form (Fig. 357, f), and consists of kidney-shaped, 2-valved cases, which contain antheridian or spermatozoidal cells (Fig. 358), and roundish or four-sided bodies, called oophoridia, opening by 2 valves, and containing 4 large spores (Fig. 359). In the interior of the latter a pro-embryo is developed, in which archegonia are produced (Fig. 400), and thereafter impregnation gives rise to the germinating body. Natives both of cold and warm climates, but abounding in the tropics, and especially in insular situations. Some of the plants have emetic and purgative properties. The powdery matter contained in their fructification is inflammable, and is known as Lycopode powder or vegetable brimstone.

Nat. Ord. 270.—EQUISETACEÆ, the Horse-tail order (Fig. 355).—Cryptogams having rhizomes or underground stems, bearing hollow, striated, siliceous branches, which are jointed and have membranous sheaths at the articulations. The place of leaves is supplied by green-coloured branchlets, which are sometimes verticillate. The fructification consists of cone-like bodies bearing peltate polygonal scales, under which are spore-cases opening inwards by a longitudinal fissure, and inclosing spores with 2 hygrometric clubshaped elaters (Fig. 9). The plants have a confervoid prothallus, and on it antheridian and archegonial cells are developed. Found in ditches and rivers in all parts of the world, both warm and cold. A large amount of silica is found in the cuticle of the Horse-tails, associated also with

fluorine. The rhizomes contain starch.

Nat. Ord. 271. - Musci, the Moss order (Fig. 361). - Erect or creeping, terrestrial or aquatic plants, with cellular stems, bearing minute cellular leaves. The organs of fructification consist of cylindrical, pear-shaped, or ellipsoidal stalked sacs, containing antheridian cells with phytozoa (Fig. 348), and of spherical or obovate archegonia, from which, after impregnation, are developed urn-shaped sporangia (Fig. 393), supported on stalks called setæ, and containing germinating spores. The sporangia have a calyptra, an operculum, and frequently a peristome, consisting of processes called teeth (Fig. 20), which are either 4 or some multiple of that num-

¹ For full details in regard to structure and reproduction in the different Cryptogamic natural orders, see pages 142 and 155.

Botany. ber. They are found in all parts of the world, and abound in moist temperate regions. Species between 1100 and 1200. There are two divisions of the order. Sub-order 1. Andræaceæ, Split-mosses; Sporangia calyptrate, splitting longitudinally into 4 equal valves, which are kept together at the summit by a persistent operculum. Sub-order 2. Bryaceæ, true Urn-mosses; Sporangia calyptrate, opening at the summit, and not by valves.

Nat. Ord. 272.—HEPATICÆ, the Liverwort order (Fig. 362).—Plants having a cellular axis of growth which bears leaves on a thallus (Fig. 362). Antheridia (Fig. 363, a) and archegonia (Fig. 349) are placed either in the substance of the thallus, or on sessile or stalked processes. The stalks support sporangia or peltate sporangiferous receptacles. Sporangia sometimes open by valves, and bear elaters. The plants are generally distributed both in cold and warm climates, and more especially inhabit damp places. Some of the species of *Marchantia*, especially *M. hemisphærica*, have been recommended as poultices in cases of Anasarca. The following are the divisions of the order:—Sub-order 1. Jungermanniaceæ, the Scale-moss tribe; Sporangia opening by 4 valves, the spores mixed with elaters. Sub-order 2. Marchantiaceæ, the true Liverwort tribe; Sporangia not opening by valves, bursting irregularly, spores mixed with elaters. Sub-order 3. Ricciaceæ, the Crystalwort tribe; Sporangia not opening by valves, and having no elaters.

SUB-CLASS II .-- THALLOGENÆ, THALLOPHYTA, OR CELLULARES.

Nat. Ord. 273.—Lichenes, the Lichen order (Fig. 364).— Cellular plants, growing on stones, on the surface of the earth, or on trees, and taking up nourishment by all points of their surface, having a foliaceous, crustaceous, or leprous thallus (Fig. 364). Their fructification consists of thecæ or asci, containing 4, 8, 12, or 16 sporidia (Fig. 346). The thecæ are often mixed with paraphyses, and by their union form circular, cup-shaped, or linear masses, which are called There are also spermogones or conceptacles, containing cells with antherozoa, which are motionless, and have received the name of spermatia. The spermogones are either in the substance of the thallus, or superficial, and the spermatia are discharged through a pore. Between the upper and lower thalloid layers, green cells, called gonidia (Fig. 365), are found. Lichens are found in various parts of the world. The pulverulent species are the first plants which cover the bare rocks of newly-formed islands. of the Lichens are used for dyeing, others are employed as articles of food and medicine. Some Lichens are aromatic, and a fragrant powder called Cyprio at Rome is in part made from them. Oxalate of lime exists largely in some species, more especially in Variolarias. islandica, Iceland-moss, contains starch, along with a bitter principle; it has been used as a tonic and demulcent. Cladonia rangiferina, is called Reindeer-moss, on account of supplying food for that useful animal. Lecanora tartarea, called in commerce Rock-moss, supplies the dye denominated Cudbear. Roccella tinctoria is one of the Lichens imported under the name of Orchella-weed. The colouring matter is called Archil or Orchil; it is used for dyeing purple and red.

Nat. Ord. 274.—Fungi, the Mushroom order (Fig. 367).* -Cellular plants, with a spawn, mycelium (Fig. 18, m), by which they are nourished, and which bears organs of fructi-fication of various kinds. Spores are produced, which are either naked (Figs. 18 and 368), or inclosed in thecæ and mixed with elaters. There appear to be antheridian cells, containing spermatozoids, by the action of which on archegonial cells germinating spores are developed. In Agarics (Fig. 367) the mycelium bears tubercles inclosed in a volva, which ruptures so as to allow of the development of the stalked pileus, with its lamellæ and hymenium. This order contains esculent

and poisonous plants; the genus Agaricus, to which the true Botany. Mushroom belongs, contains both, and it is not easy to give rules for distinguishing the two kinds. Their qualities seem to depend in part on the mode in which they are prepared for food, and this may account for species which are eaten in some countries having proved poisonous in others. Fungi contain much nitrogen in their composition, and they do not appear to give out oxygen gas. They are often developed with great rapidity. The spawn spreads under ground, or in the interior of living or dead organisms, and when favourable circumstances occur, the fructification bursts forth with astonishing quickness. Many of them are developed on living plants, and cause disease and death by their parasitic growth. Agaricus campestris is the common Mushroom of Britain; it is distinguished in part by its pink gills. A. Georgii is another edible British species, which sometimes attains a large size. A. prunulus is said to be the most delicious Mushroom. Amanita muscaria* is a poisonous species, which produces giddiness and *Plate narcotic symptoms. Morchella esculenta, Morel, is an edi-CXXXVL ble Fungus. Penicillium glaucum is the common Mould fig. 1. developed wherever organic substances are in fitting conditions of moisture and temperature. The Vinegar-plant seems to be the abnormally developed mycelium of P. glaucum, or perhaps P. crustaceum. Sphæria sinensis, is a Fungus parasitic on a caterpillar. It is a celebrated drug in

Nat. Ord. 275.—CHARACEÆ, the Chara order (Fig. 21).— Aquatic plants composed of parallel cellular tubes, which give off whorled branches (Fig. 21), and which are often incrusted with carbonate of lime. In their tubes, rotation is observed. Their reproductive organs consist of globules containing antheridian cells with spirilla, and spiral nucules containing germinating cells or spores (Fig. 373). Charas are found submersed in stagnant fresh or salt water in various part of

China. Tuber is the genus which embraces the various kinds of Truffle (Fig. 366), an underground Fungus, which

is scented out by dogs and pigs.

the world. They have a fetid odour. Nat. Ord. 276.—Algæ, the Seaweed order (Fig. 39).— Cellular plants, found in the sea, in rivers, lakes, marshes, and hot springs, all over the world, consisting of a brown, red, or green thallus, sometimes stalked, which bears the organs of fructification (Fig. 39). These consist of antheridian cells containing phytozoa, and of others containing germinating spores of different kinds (Figs. 370 and 371). These organs of reproduction are often united in the same conceptacle (Fig. 369 b). In other cases, they are on different parts of the same plant, or even on different plants. The spores sometimes have moving cilia, and are called zoospores (Fig. 8), at other times four are united so as to constitute tetraspores (Fig. 371). In some of the filamentous Algæ there is a conjugation of 2 cells, so as to produce a spore (Fig. 19), in others there is a fissiparous division of cells (Fig. 13). Species of Algæ abound both in salt and fresh water, whether running or stagnant, and in mineral springs. There are three colours in Algæ, grass-green, olivaceous, and red. Some Seaweeds are microscopic, others growing in the depths of the Pacific have trunks exceeding in length those of the tallest forest trees, and fronds rivalling the leaves of the Palm. Many of the lower Algæ approach nearly to some of the lowest animal forms, and it is difficult to form a line of demarcation. Species of Navicula, Pleurosigma, and other allied forms, are placed by some among Diatoms, by others among animals. Peculiar forms are met with in diseased states of the stomach and bladder, which are referred to Diatoms; one of them is called Sarcinula ventriculi. Achlya prolifera is sometimes produced on the gills of gold fishes and other animals in a state of disease. The order has been divided in the following manner:-Sub-order 1. Melanospermeæ or Fucaceæ, brown-coloured Seaweeds (Fig. 39); Marine plants of an olive-green or olive-brown colour, con-

*Plate CXXXVI.

Botany. sisting of multicellular fronds, which assume a thalloid or a filamentous form; fructification consisting of conceptacles, containing archegonial and antheridian cells, the latter containing phytozoa, the former being developed as germinating spores. Sub-order 2. Rhodospermeæ or Ceramiaceæ, rose-coloured Seaweeds (Fig. 371); Marine plants of a rose-red, purple, or red-brown colour, leafy, cylindrical or filamentous; fructification consisting of conceptacles containing spores, and clavate filaments considered as antheridia. The spores are arranged often in fours, and are called tetraspores. Suborder 3. Chlorospermeæ, or Confervaceæ, green-coloured Seaweeds (Fig. 17); unicellular or multicellular (Figs. 11 and 19), marine or fresh-water plants; the cells contain a green (rarely purple or red) endochrome; reproduction effected by conjugation of cells (Fig. 19); zoospores (Fig. 8) often produced. Sub-order 4. Diatomaceæ, Brittleworts (Fig. 13); plant a frustule, consisting of a unilocular or a septate cell; cells composed of 2 symmetrical valves; gemmiparous increase by self-division; reproduction by conjugation and the formation of sporangia. There are 2 distinct sections: a. Diatomeæ; invested with a siliceous epidermal covering, and found both in salt and fresh water. b. Desmidieæ; minute fresh-water plants of a green colour, without a siliceous epidermis. Agardh divides Algæ into Fucoideæ, corresponding to Melanospermeæ of Harvey, Florideæ equi-

valent to Rhodospermeæ, and Zoospermeæ corresponding Botany. to Chlorospermeæ. The primary divisions into orders he bases on the structure and development of the sporiferous nucleus.

Many of the Algæ supply nutritious matter, and are used as food. Among them may be noticed species of Rhodymenia (Dulse), Sphærococcus, Alaria, Iridæa, Laminaria, Porphyra, Ulva, (Laver), and Gelidium. The edible nests formed by swallows in China have been supposed to be made of portions of gelatinous Seaweeds. Chondrus (Sphærococcus) crispus and C. mammillosus, receive the name of Carrageen or Irish Moss. Their fronds consist in great part of a substance somewhat allied to starch, which is extracted by boiling in water. On cooling it forms a jelly. Diatomaceæ occur in the form of extensive deposits in various parts of the world. It is said that the city of Richmond, in Virginia, is built on a stratum of Diatomaceous remains 18 feet in thickness. Extensive tracts in arctic and antarctic regions are covered with similar relics of a former vegetation. Laminaria saccharina yields upwards of 12 per cent. of Mannite. Nostoc edule is employed in China as an article of diet. Sargassum bacciferum constitutes the Gulfweed, which has been noticed by all who have crossed the Atlantic. The Gulf-weed has never been found attached, but always floating.

PART III.

GEOGRAPHICAL BOTANY, OR THE GEOGRAPHICAL DISTRIBUTION OF PLANTS.

This department of Botany is one of vast extent and importance, and the consideration of it would require much more space than can be allotted to it in the present article. All that we can attempt to do is to give some general facts regarding the distribution of plants over the globe, and to point out some of the causes which regulate this distribution.

The nature of the vegetation covering the earth varies according to climate and locality. Plants are fitted for different kinds of soil, as well as for different amounts of temperature, light, and moisture. From the Poles to the Equator there is a constant variation in the nature of the Flora. Between the Lichens and Mosses of the Arctic and Antarctic regions, and the Palms, Bananas, and the Orchids of the Tropics, there is a series of regulated changes in the number and forms of the members of the vegetable kingdom. The same thing is observed in the vegetation of lofty mountains at the Equator, in descending from their summit to their base. As we proceed from the Poles to the Equator, vegetation increases in amount and in variety. From a region characterized by the presence of Lichens, Mosses, Saxifrages, and Gentians, we come to that of Cruciferæ and

Umbelliferæ; we then reach the grassy pastures, and the Coniferous and Amentiferous trees of temperate regions; and passing through the districts of the Vine, the Orange, and the dwarf Palm, to those of the Date, Coffee, Cotton, Sugar-cane, and Pine-apple, we arrive at the luxuriant vegetation of Equatorial regions. In this progress, as Humboldt remarks, we find organic life and vigour gradually augmenting with the increase of temperature. The number of species increases as we approach the Equator, and decreases as we retire from it. Each zone, however, has its own peculiar features. The Tropics have their variety and grandeur of vegetable forms, while the North has its meadows and green pastures, and the periodical awaking of nature in spring.

I.—INFLUENCE OF CLIMATE, MORE ESPECIALLY OF TEMPERATURE AND MOISTURE, ON THE DISTRIBU-TION OF PLANTS.

In determining the effects of climate on vegetation, our attention is chiefly directed to temperature and moisture,—to the daily, monthly, and annual distribution of heat, and

Botany.

Botany. to the amount of rain. We must also take into account light, the nature of the plant, its exposure, and many other causes, the effects of which are by no means easily estimated. They operate, however, usually within narrow limits, heat and moisture being the general agents. While in a given place the quantity of heat received varies according to different circumstances, it is found that the mean is pretty uniform. The quantity of heat is modified by winds and moisture. In China, for instance, the N.E. monsoon causes a great depression of temperature. The general preponderance of moist warm winds over dry cold ones is the reason why mild winters are more frequent in Europe than severe ones. Mountain chains, by intercepting winds, often produce a marked effect on climate. The effect of the sea in modifying the temperature is seen in insular climates, which are more equable than those of vast continents. Marine currents have also a decided influence on temperature. Thus the gulf-stream in the Northern Atlantic Ocean carries warm water towards the Arctic regions, and materially affects the temperature of the coasts around which it flows; while the Peruvian coast current, by bringing cold water from the antarctic regions towards the Equator, also modifies temperature. The temperature of the globe varies both as regards latitude and altitude, and vegetation at the same time undergoes changes. Latitudinally the globe, as regards temperature, may in a general way be divided into a tropical region extending from the Equator to 23° 28'; a sub-tropical, as far as 40°; a temperate from 40° to 60°; and a cold region beyond 60°. In a hypsometrical or altitudinal point of view, different zones of temperature are recognised, corresponding more or less with those of latitude. On an average, it may be said, that there is a difference of 1° of Fahrenheit for every 300 or 400 feet of ascent, and a difference of 1° of the thermometer in the boiling point of water for every 550 feet of ascent.

Each species of plants can bear a definite range of temperature. A certain amount of heat is also required during a given period of time, in order that a plant may be enabled to perform all its functions properly. Although a plant may continue to live in a certain climate, it may not thrive. The only true indication of climatal adaptation is, that the plant can perfect its seed and produce its various secretions. The latitude of a place does not at once tell the range of temperature. Many places in the same parallel of latitude differ widely in this respect. Lines, called Isothermal, have been drawn through places in which the mean annual temperature is the same, and it is found that while at the Equator these correspond nearly with the lines of latitude, as we recede from the Equator the two are widely separated. Yearly isotherms run in curves, rising in their course from ' the east of America towards the west of Europe, and sinking towards the south in the interior of the Continent. The yearly isotherm of 50° passes through latitude 42° 30' in the east of America, 51° 30' in England, 47° 30' in Hungary, and 40° in Eastern Asia. The want of conformity between the isothermal and latitudinal lines will be easily understood, when we consider that a place having a moderate summer and winter temperature may have the same annual mean as one having a very cold winter and a very warm summer. The vegetation in such districts would, however, be very different, and thus the annual isotherms are not sufficient for the purposes of botanical geography. Plants which stand the winter of London will not withstand the cold of places in Hungary in the same annual isotherm. In estimating, therefore, the effect of different climates on vegetation, attention must be paid also to the summer and winter heat. Lines passing through places with an equal mean summer heat are called Isotheral, while those indicating an equal mean winter temperature are called Isocheimal or Isocheiminal. The latter in continents bend considerably towards the south, while the former bend towards the north,

but approach nearer the parallels of latitude in the interior Botany. of continents. Some plants require a long period of winter repose and a few weeks only of warm and continued summer; others demand a dry season succeeded by a moist one. Some require a hot summer after an extremely cold winter of moderate duration; others succeed in a climate where the temperature of both seasons is moderate. In determining the limits of distribution in the vegetable kingdom, we must know the mean monthly and the mean daily temperature during those periods when vegetation is active. We. must ascertain the number of days which a plant requires to produce successively its leaves, flowers, and fruit, and we must estimate the mean temperature during that period. The conditions which define the limits of a plant require that we should know at what degree of temperature its vegetation begins and ends, and further, the sum of the mean temperatures during that time.

Light and heat are so intimately connected, and so generally accompany each other, that the laws of the one are very nearly those of the other. Both of them are of the utmost importance in vegetation. Light is concerned in the various functions of plants. The physiological action of the leaves cannot go on without it, and the activity of vegetable life is in no small degree dependent on it. Some plants require full exposure to light, others luxuriate in the shade. The difference of the intensity of light in different countries influences the secretions of plants, and has a certain effect on the nature of the vegetation. While the chemical constitution of the atmosphere is nearly the same everywhere, This depends both on elevaits density varies much. tion and on the matters which may be suspended in it. It is probable that the varying density of the atmosphere at different elevations produces little or no effects in comparison with those which result from the modifications which the temperature, light, and humidity of the air undergo.

Moisture is an agent which exerts a powerful influence on the distribution of plants. Vegetation develops itself only when moisture is present. Very dry regions are deficient in vegetable productions, while the luxuriance of tropical vegetation is connected with great heat and moisture. Plants differ in regard to the quantity of moisture they require. Some are of a loose, spongy texture, with large, soft leaves, little or no pubescence, and many stomata, and demand a great deal of water. Others, growing in sandy, dry situations, where little rain falls, are firm and succulent, and often have long hairs and few stomata. The hard dry texture of the leaves of Banksias and other Australian plants, seems to be connected with the small amount of moisture in the atmosphere. Forests have a marked effect on the humidity of climates, and the felling of them has often been productive of very injurious consequences, by diminishing the quantity of water. In warm climates, the dry season may be said to correspond to our winter in its effects on vegetation. In some parts of South America, where no rain falls for many months of the year, the leaves during the dry season fall; buds are developed in their axils, and it is only when the wet season arrives that the trees become clothed with verdure, and the herbage appears.

Epirrheology or the influence of various physical agents on plants, is well illustrated by the variations in the epochs of foliation, defoliation, flowering, and fruiting. The unfolding of the leaves takes place at different periods of the year in different countries. Thus the Elm (Ulmus campestris) unfolds its leaves at Naples at the beginning of February, at Paris in the month of March, in England 15th April, and at Upsal about the middle of March. Schubler found in general that in the middle latitudes of Europe and North America, the flowering of plants is delayed four days for each degree of latitude towards the north. Berghaus remarks that in higher latitudes, in districts situated in the north of Germany, the development of vegetation is less re-

Botany.

Botany. tarded than in more southern positions. The delay in the period of flowering, between Hamburgh and Christiania, amounts to only 3.4 days for one degree of approach towards the north, while that between southern Germany and Smyrna, in Asia Minor, which is in the same parallel as the most southern portions of Europe, amounts for the same space to 7.4 days.

Wheat harvest begins at Naples in June, in central Germany in July, in the south of England and the middle districts of Sweden about the 4th of August. Barley harvest commences at Naples in June, in central Germany about the end of July or beginning of August, in the south of England about the 14th of August, and in the middle districts of Sweden about the 4th of August. Ripe Cherries may be had at Naples during the first days of May, at Paris and in central Germany about the end of June, and in the south of England about the 22d of July. From observations made during two years in Saxony, we find, as a mean result, that from the flowering to the ripening of the fruit, 56 days are required for Wheat, 59 for Rye, 31 for Barley, 45 for Oats. Thurmann states that in the Jura, generally speaking, a delay of 17 days in the harvest corresponds to a difference of altitude of 1000 feet. On the Alps, according to Schlagintweit, there is a delay of 11 days in the development of vegetation for every 1000 feet. Quetelet finds that in the climate of Europe every 600 or 700 feet produces a delay of about 4 days, which is equal to about 1° of latitude.

As regards the fall of the leaf, or defoliation, Berghaus remarks, that the Hazel-nut tree, the Ash, Lime, Poplar, and Maple, lose their leaves at Upsala at the very beginning of autumn; while in the neighbourhood of Naples they remain in full foliage during the whole month of November. The Apple-tree, the Fig-tree, the Elm, Birch, and different kinds of Oak, which in Paris are deprived of their leaves at the beginning of November, retain them at Naples till the end of December. In England, the Walnut is one of the first trees that loses its leaves; and after it the Mulberry, the Ash (especially when it has had much blossom), and then the Horse-chestnut.

II.—INFLUENCE OF SOILS ON THE DISTRIBUTION OF PLANTS.

Soils, or the media in which the roots of plants grow, regulate to a certain degree their distribution. In estimating this influence we must take into account the geognostic nature of the soil, its state of aggregation, its temperature, moisture, and exposure. Some plants are terrestrial, others are aquatic; some grow suspended in the air, others are parasitic. The effects produced by ordinary soils depend perhaps more on their mechanical nature than on their chemical composition. Hard, undecomposed felspar will bear a scanty vegetation, but when disintegrated and loose it affords abundant nourishment. The vegetation of limestone and trap rocks is more luxuriant than that of sandy soils. The moisture retained by aluminous soils is much greater than that by siliceous soils. Many plants seem to thrive best on chalky soils, others on siliceous, argillaceous, or peaty soils. Certain species grow only on soils impregnated with saline matters; others require to be within the influence of the sea. Parasites are often confined to peculiar species of plants.

Plants, in reference to the physical localities or stations in which they grow, have been divided into terrestrial, aquatic, marshy, epiphytic, and parasitic. Among terrestrial plants, the nature of the soil in which they grow gives rise to various groups. Arenaceous or sand plants have a peculiar character in all parts of the world, and the greater number are probably grasses. Some of them bind the loose sand by their creeping stems. Calcareous or chalk plants are found on limestone rocks. Many Orchids belong to this division, especially species of Ophrys and Cypripedium.

Saline plants are those found in maritime situations, or near salt lakes, and which seem to require much soda in their composition, and which have been called Halophytes. Among them are species of Salsola, Salicornia, and Statice. Rupestral and mural plants are those found on rocks and walls, such as species of Saxifrage, Sedum, Draba, Sisymbrium, Parietaria, Linaria Cymbalaria, Asplenium Rutamuraria, A. Trichomanes, Lichens, and Mosses. Some also grow on the ruins of old buildings, and on rubbish-heaps, &c., near the habitations of man and animals. Among these are included Nettles, Docks, Hyoscyamus, Xanthium, and Sempervivum tectorum. Plants which grow in cultivated grounds, as in fields and gardens, may be said to form a special division. Among them may be noticed Centaurea Cyanus, Lychnis Githago, Spergula arvensis, Sinapis arvensis, Lolium temulentum, Stellaria media, species of Lamium, Chenopodium and Euphorbia.

Plants of uncultivated ground are:—Meadow and Pasture plants, such as Grasses, Trefoils, Clovers, species of Ranunculus, Veronica, Campanula, Galium, and Myosotis, Bellis perennis, Lotus corniculatus, Pimpinella Saxifraga, Gentiana campestris: Heath plants, such as Calluna vulgaris, the species of Erica, Juniperus communis, species of Ledum, Andromeda, and Polytrichum: Forest plants, growing in woods, such as the different kinds of trees; and the plants which grow under their shade, as Oxalis Acetosella, Trientalis europæa, Linnæa borealis, Geum rivale, Hepatica triloba, Vaccinium Myrtillus, and species of Orchis: Bush-plants, or those growing in bushy places, as Origanum vulgare, Corydalis bulbosa, Vincetoxicum officinale: Mountain plants, which vary much according to elevation. and which include species of Saxifraga, Gentiana, Primula, Rhododendron, Salix, Cyperaceæ, Juncaceæ, Labiatæ, &c.: Hedge plants, such as Hawthorn and Sweet-briar, and the plants which twine among their branches, as Lonicera, Humulus, Bryonia, Tamus, Člematis, Lathyrus, as well the species of Viola and Adoxa, which grow at their roots.

Aquatic plants may either grow in salt or in fresh water. Among the former are marine species, such as the common species of Fucus, and other Seaweeds which grow buried in the ocean, and the Sargassum, or Gulf-weed, which floats on its surface; with them may be included such Phanerogamous plants as Zostera. Among the latter are some which root in the mud, and flower above the water, as species of Nymphæa, Nuphar, Potamogeton, Ranunculus, Utricularia, and Sagittaria; others flower under water, as Subularia aquatica; while others float in the water, as species of Lemna, Pistia, Stratiotes, and various green fresh-water Algæ. Some aquatics are fluviatile, as Ranunculus fluviatilis and Œnanthe fluviatilis; others grow in fresh clear

water springs, or near them, as Montia fontana.

Marshy plants are those which grow in different kinds of wet soil. Some of them, as Comarum, Menyanthes, species of Bidens, Œnanthe, Cicuta, and Carex, grow in very wet places, which are not always easily accessible; others, as Primula farinosa, and Pinguicula alpina, grow in firmer, peaty soil. To this class may be referred certain amphibious plants, which generally grow submerged, but which can live in dry soil. Among them are included various forms of Ranunculus, Polygonum amphibium, Nasturtium amphibium, Limosella aquatica, as well as species of Rhizophora and Avicennia, which are found in warm countries at the muddy mouths of rivers.

Epiphytic plants are those which send their roots into the air, and grow attached to other plants. Among them are enumerated numerous species of tropical orchids (Fig. 70), and other air-plants, such as species of Tillandsia and Pothos. Parasitic plants are those which derive nourishment from other plants. Among them are included those growing on living vegetables, such as species of Loranthus, Viscum *Plate (Fig. 488), Lathræa, Orobanche, Cuscuta* (Fig. 426), Raf-cxxv.

Botany. flesia (Fig. 549), and many Fungi; those growing on dead vegetable or animal tissues, as the various Mould-plants (Figs. 422 to 425).

> III .- DISTRIBUTION OF CLASSES, ORDERS, GENERA, AND SPECIES OF PLANTS OVER THE GLOBE.

Some plants are generally distributed over the globe, occurring in both hemispheres, and having an extensive latitudinal range; others are restricted and endemic in their distribution. There are numerous interesting facts in regard to geographical distribution in Hooker's Antarctic Flora, a work from which many of the following examples are taken. Trisetum subspicatum is a Grass having a very wide range. It extends from Tierra del Fuego over the whole of the Peruvian Cordilleras, and over the Rocky Mountains to Melville Island, Greenland, and Iceland; it is found in the Swiss and Tyrolese Alps, on the Altai, in Kamtschatka, and in Campbell's Island. The range is from 54° S. Lat. to $74\frac{1}{2}$ ° N. Lat., through $128\frac{1}{2}$ degrees of latitude. Drimys Winteri* extends over no less than 86 degrees of latitude, or 5160 geographical miles, forming at the southern limit of its growth one of the trees which advance nearest to the antarctic circle, and reaching as high a latitude as any flowering plant, save the solitary Grass of the South Shetland Islands. Gentiana prostrata has a great range, both in longitude and latitude. In southern Europe it inhabits the Carinthian Alps between 6000 and 9000 feet high; in Asia, it occurs on the Altai Mountains about N. Lat. 52°; in America, on the tops of the Rocky Mountains, in Lat. 52° N., at an elevation of 15,000 to 16,000 feet; and on the east side of the Andes of South America, in 35°S. It descends to the level of the sea at Cape Negro, in the Straits of Magalhaens, in Lat. 53° S.; and at Cape Good Hope, in Behring's Straits, Lat. 681° N. Potentilla anserina is widely distributed both in the northern and southern hemispheres. It grows throughout Europe, from the shores of the Mediterranean to the Arctic Sea; over all Asia to the north of the Altai range; in North America, from Lat. 40° to Whalefish Island in 70° N. Lat.; and from the Oregon River to Kotzebue's Sound on the west coast. Epilobium tetragonum, a British plant, extends from Canada to Fuegia. Callitriche verna is universally diffused through the temperate regions of both hemispheres. Many species in the Falkland Islands are identical with those found in Iceland. Galium Aparine is a British plant, found at the Cape of Good Hope, at the Straits of Magalhaens, in the island of Chiloe; and in North America it ranges between the latitude of Fort Vancouver and the Mississippi River. Cryptogamic cellular plants have generally a very wide range; many of them are universally distributed.

Some plants which have a great latitudinal range are restricted to a narrow space as regards longitude. This is the case with the species of Erica, which extend from the Cape of Good Hope to northern regions. Certain species of Rhododendron, Magnolia, Azalea, Actæa, and Andromeda, occur on the east of the Rocky Mountains, and are not found on the western side. In the western part of Ireland we meet with Daboecia polifolia, Erica mediterranea, and Arbutus Unedo, which are not met with in other parts of Britain, and which again appear on the mountains of Asturias. On the western side of the Cordilleras of Chili, Calceolarias grow, which are not found on the eastern side. Lobelia Dortmanna seems to be confined to the western European coun-

While some plants are generally and widely distributed, others are limited to particular countries, and sometimes confined within very narrow limits. The floras of the different quarters of the world contain certain plants, which are restricted to them, and some which are only found in a few localities. One region in the Andes is marked by the occurrence of species of Bejaria, and another by Cinchonas.

Certain plants belonging to the natural order Polemoniaceæ Botany. are peculiar to California; an Orchid, called Disa grandiflora, is confined to Table Mountain; Codon Royeni and Protea acaulis are restricted to a few localities at the Cape of Good Hope. Numerous instances of a similar kind may be given, more particularly in the case of islands. The flora of islands near continents partakes of the character of that of the mainland. Those remote from continents, however, have often a more or less endemic flora. St Helena had a peculiar flora, which has been strangely altered by foreign introductions. Pringlea antiscorbutica, Kerguelen's Land Cabbage, is an interesting plant growing on an island, the remotest of any from a continent, and which, according to Hooker, yields, besides this esculent, only 17 other flowering plants.

We sometimes meet with marked centres, where the maxima of the genus of an order, or of the species of a genus, occur, the number of the genera or species diminishing as we recede from these centres, and ending perhaps in a solitary representative in some distant country. Gentians and Saxifrages have their maxima in the European Alps; Eriocaulons have their great centre in Brazil, but a few species are found in other countries. Epacridaceæ are restricted to Australia. The genus Viola has two marked centres, one in Europe and another in America. The form of the European and American species are quite distinct. The maximum of the genus Erica is at the Cape of Good Hope; but members of the Heath family extend to northern regions in the form of Erica Tetralix, E. cinerea, and Calluna vulgaris. The tropical Myrtaceæ have Myrtus communis to represent them in Europe, Leptospermeæ in Australia, and Metrosideros lucida in Lord Auckland's group, Lat. 501° S.

An order, or a genus, or a species, in one country is occasionally represented in another by forms which are either allied, or have a physiognomic resemblance. There is thus sometimes a repetition of resembling or almost similar forms in countries separated by seas or extensive tracts of land. The Ericaceæ of the Cape have in Australia a representative in the nearly allied Epacridaceæ; the Cactaceæ of America are represented by certain succulent forms of Mesembryanthemaceæ and Euphorbiaceæ in Africa; and by some Crassulaceæ in Europe. Trientalis europæa has a representative form in America, T. americana; Cornus suecica occurs in Europe, C. canadensis in Canada. Empetrum nigrum, in arctic regions, has E. rubrum to take its place in the antarctic; Pinguicula lusitanica, in the northern hemisphere, has P. antarctica closely resembling it in the southern; Hydnora africana and H. triceps in South Africa are represented in South America by H. americana.

The mode in which the globe has been clothed with vegetation, has given rise to much discussion. We know from the Sacred Record, that on the third day of the Creation the earth brought forth grass, and herb yielding seed after his kind, and the tree yielding fruit after his kind; but whether the whole earth was at once clothed with vegetation, or certain great centres were formed, whence plants were gradually to spread, we have no means of knowing. The endemic limitation of certain orders, genera, and species, would certainly lead to the opinion, that, in many instances, there have been definite centres, whence the plants have spread only to a certain extent. But the general distribution of other tribes of plants, and the occurrence of identical species in distant parts of the world, would favour the view, that countries with similar climates had originally many species of plants in common. In the case of Grasses, we would naturally suppose that they must have been produced in their social state, forming pasture for the nourishment of animals; and such we might conjecture to be the case with social plants in general.

Edward Forbes advocates strongly the view of specific

Botany. centres, and endeavours to account for the isolation of certain species or assemblages of plants from their centres, by supposing that these outposts were formerly connected, and have been separated, by geological changes, accompanied with the elevation and depression of land. Schouw opposes this. He thinks that the existence of the same species in far distant countries is not to be accounted for on the supposition of a single centre for each species. The usual means of transport, and even the changes which have taken place by volcanic and other causes, are inadequate, he thinks, to explain why many species are common to the Alps and the Pyrenees on the one hand, and to the Scandinavian and Scotch mountains on the other, without being found on the intermediate plains and hills; why the flora of Iceland is nearly identical with that of the Scandinavian mountains; why Europe and North America, especially the northern parts, have various plants in common, which have not been communicated by human aids. Still greater objections to this mode of explanation, he thinks, are founded on the fact that there are plants at the Straits of Magalhaens, and in the Falkland and other antarctic islands, which belong to the flora of the arctic pole; and that several European plants appear in New Holland, Van Diemen's Land, and New Zealand, and which are not found in intermediate countries. Schouw, therefore, supposes that there were originally not one, but many primary individuals of a species.

Provision has been made for the extension of plants over the globe. The usual modes of transport are man, tides of the sea, rivers, winds, and birds. The Coco-nut wafted on the ocean is able to resist the action of the salt water by means of its fibrous covering, and lands on islands and shores in a state fit for germination. In this way recently produced coral islands are covered with vegetation. The hairy fruits and seeds of many plants are wafted to a distance by the winds, and rivers carry down the seeds of plants which have grown at their source. Birds which feed on pulpy fruits, often deposit the hard seeds at distant parts. Man, in his migrations, has distributed many plants, including common weeds, as well as plants useful for food or

clothing.

Great changes have taken place in the distribution of many useful plants, chiefly by the agency of the Caucasian races, who have transplanted to their own countries the characteristic plants of other nations. Thus Schouw remarks they have brought the Apricot, the Peach, and the Almond, from Asia Minor and Persia, and the Orange from China; they have transplanted Rice and Cotton to the Mediterranean coasts; they have brought the Maize and Potato from America to Europe. They have also carried their own characteristic plants to their colonies, and have transported into various climates useful and ornamental vegetable productions. European Corn plants have been widely spread through North America, in Mexico, the elevated countries of South America, Chili, Buenos Ayres, in South Africa, in the temperate parts of Australia and Van Diemen's Land. The Vine has been spread to Madeira, the Canary Islands, South Africa, and the high lands of South America. The Coffee-tree and Sugar-cane have been transplanted by man into the West Indies and Brazil; the Nutmeg and Clove into the Mauritius and Bourbon, and various West India islands; plantations of Tea have been formed in Brazil, Java, and India; Rice and Cotton have been cultivated in the warmer parts of North America and Brazil, and New Zealand Flax in New Holland.

The consideration of the distribution of the Cereal grains and of the Potato is a subject of much interest. The former have been so long cultivated, and so extensively spread, They that it is difficult to discover their native country. are not seen in a wild state, unless it be true, as Esprit Fabre says, that Ægilops ovata is the wild condition of Wheat, and they have a wide geographical range, so as to

be fitted for various climates. Rice is the grain which fur- Botany. nishes food to the greatest number of the human race; it is extensively used in warm countries, and more especially in China. Maize bears the greatest range of temperature, and succeeds in the hottest climates. Millet also is associated with it in hot countries. Wheat succeeds best on the limits of the sub-tropical region, and, as we proceed north, is succeeded by Rye, and then by Barley and Oats, which extend farthest north in Europe.

IV.—PHYSIOGNOMY OF VEGETATION IN DIFFERENT QUARTERS OF THE GLOBE.

In this department of botanical geography we consider plants according to the distribution of forms, marking the predominance of this or that form of plants by the absolute mass of its individuals or by the impression it makes from the character given to the flora. The prevalence of a single form will often produce a much greater physiognomic effect than the number and variety of the floral productions. Hinds says that a general physiognomic impression is sometimes conveyed by the prevalence of colour. Social plants in an especial manner, affect the landscape from growing in There are certain marked vegetable forms which are concerned in determining the aspect or physiognomy of nature in different countries. Some of these leading forms coincide with natural orders; at other times, several distinct botanical groups require to be united.

The Palm Form (Fig. 82)—gives a marked character to the warmest regions of the globe, between 10 deg. north and 10 deg. south Lat. The true Palm climate has a mean annual temperature of 78.2 deg. to 81.5 deg. F. South America is conspicuous for the beauty and number of its Palms. With the Palm form has been associated the Cycadaceous order (Fig. 556),* which resembles it somewhat in the ap-*Plate pearance of its naked stems and tufts of pinnated leaves.

The Banana and Plantain Form (Fig. 86)—is usually associated with the Palms in the torrid zone. In this form the physiognomist includes the natural orders Musaceæ, Zingiberaceæ, and Marantaceæ. The plants representing this form have succulent herbaceous stems and long delicately-veined verdant leaves.

The Malvaceous Form*—represented in warm climates *Plate by trees with thick trunks, large soft cordate or lobed leaves, CXIV. and gorgeous flowers. It includes the orders Malvaceæ, Byttneriaceæ, Sterculiaceæ, and Tiliaceæ.

The Mimosa Form—is represented by Leguminosæ, with delicately pinnate leaves (Fig. 132), and is met with both in warm and in temperate regions. It is not seen in the temperate zone of Europe, though found in the United States.

The Heath Form—belongs especially to the African continent and islands, as well as to Australia. Under it are included the species of Erica (Fig. 503) and Calluna, the Epacridaceæ of Australia, the sub-order Diosmeæ of the order Rutaceæ, and some Proteaceæ.

The Cactus Form (Figs. 142 and 483)—with its peculiar jointed or spherical or polygonal stems without true leaves, is exclusively American. Some of the stems become hard and ligneous, and are very indestructible. Certain Euphorbias may be said to represent this form in Africa.

The Orchideous Form (Fig. 70)—is represented by the epiphytes which enliven the rocks and the trunks of trees in tropical climates, and which are distinguished by the animal

shapes and colouring of their flowers.

The Casuarina Form—consists of leafless trees, with branches resembling those of Equisetums, found chiefly in the islands of the Pacific Ocean and in India. Along with phyllodiferous Acacias and some Myrtaceæ, Casuarinas give a uniform character to the Tasmanian flora

The Coniferous Form-is represented by the needleleaved trees of northern regions, the Pines, Cypresses, and Thujas; and by the broader-leaved Dammara and Salis-

Botany. buria of more southern regions. In the Himalaya and the Mexican mountains Coniferous and Palm forms are associated.

*Plate CXXXV.

The Pothos Form-prevails chiefly in the tropics, and is represented by Pothos, Dracontium, Caladium, and Arum.* They have succulent stalks, large thick-veined leaves, and flowers more or less spathaceous.

The Liane Form-is represented by the twining ropeplants, the Paullinias, Banisterias, Bauhinias, Bignonias, Passifloras, and Aristolochias, of the hottest parts of South America, and the Hop and Vine of temperate climes.

The Aloe Form-consists of plants with succulent tufted leaves, found in arid regions, often growing singly, and imparting, according to Humboldt, a peculiar melancholy character to the tropical regions in which they are found.

The Gramineous or Grassy Form—illustrated in tropical regions by arborescent Bamboos, and in temperate regions by meadows and pastures. Along with true Grasses are associated Cyperaceæ, Juncaceæ, Restiaceæ, and Eriocaulonaceæ. The genus Carex, is one of the Grassy forms of

cold regions.

The Fern Form—gives a character to the landscape of warm and tropical regions. Like Grasses, Ferns have a gigantic appearance in the hotter parts of the globe. On the Andes they are associated with the Cinchona trees. In temperate insular climates, such as that of New Zealand,

Ferns predominate.

The Liliaceous Form-includes the orders Liliaceæ, Amaryllidaceæ, and Iridaceæ. In Southern Africa the species of Amaryllis, Ixia, and Gladiolus, with their ensiform leaves and gorgeous blossoms, represent this form. In America the Liliaceous form is represented by Alstræmerias and species of Pancratium, Hæmanthus, and Crinum, which, however, are less social than the European Iri-

The Willow Form—is represented by the species of Salix which spread over the northern hemisphere from the equator to Lapland. They increase in northern countries.

The Myrtle Form—gives a peculiar character to the south of Europe, especially the Mediteranean islands; to New Holland, in species of Eucalyptus, Melaleuca, Metrosideros, and Leptospermum; and to the district of the Paramos in the Andes, where certain species of Escallonia, Symplocos, Myrica, and Myrtus, are found.

The Melastoma Form—is represented by the species of Melastoma and Rhexia, with their ribbed and beautifully veined leaves, which abound in tropical America, and some of which ascend to 10,000 and 11,000 feet on the Andes.

The Laurel Form—is represented in South America by species of Laurus and Persea, as well as by some of the Guttiferæ.

The Form of Dicotyledonous Trees—is represented in northern climates by the Oak, Beech, Elm, Horse-chestnut, Poplar, Alder, and Birch; in warmer climates by the. Olive, and in the hottest regions by the large-leaved Breadfruit trees and Cecropias.

The Moss Form-is characteristic of cold regions. Hooker mentions, that in New South Shetland there are specks of Mosses struggling for existence. In Cockburn Island five

Mosses are found.

The Lichen Form—is associated with Mosses, and may be said to extend still farther. It forms the limit of terrestrial vegetation. On Deception Island Lichens only exist.

V.—THE STATISTICS OF VEGETATION OVER THE GLOBE.

This subject involves the consideration of the number of known vegetable species in the world, their numerical distribution, and the relative proportion of classes, orders, genera, and species in different countries. In the present

imperfect state of our knowledge of the floras of different Botany. countries, it is impossible to tell the exact number of species of plants in the globe. Those known at the present day, described and undescribed, amount probably to nearly 120,000, and from this estimates have been made of the total vegetation, the numbers varying from 150,000 to 200,000. The following is the estimated number of known and described plants :-

	Genera.	species.
Acotyledonous plants	1,400	15,000
Monocotyledonous plants	1,450	14,000
Dicotyledonous plants	6,300	67,000
	9.150	96,000

The relative numerical proportion of these great classes of plants varies in different quarters of the world. It is estimated that Cryptogamic plants are to Phanerogamous plants as 1 to 7. In northern and alpine regions the proportion of the former increases. In equatorial regions, Monocotyledons are to Dicotyledons in the proportion of 1 to 5 or 6; in temperate regions as 1 to 4; and arctic regions as 1 to 3. In temperate and cool climates there is an increase of Monocotyledonous plants, particularly of Gramineous forms. Tropical islands in general possess proportionally more Monocotyledons than do the continents; the usual proportion in these islands is said to be 1 to 4. An equable temperature, and a rather humid climate, are favourable to Monocotyledons. They diminish both under the extreme cold of the arctic zone and the great heat of the tropics. They increase towards the southern temperate and antarctic zones. Hooker remarks, that in St Helena Monocotyledons are to Dicotyledons nearly as 1 to 5, in the Society Islands as 1 to 4.2, in the Sandwich Islands 1 to 4, in the Cape de Verd Islands 1 to 5, in the Canaries 1 to 6, in Madeira 1 to 5.4, in the Azores 1 to 4.1, in Great Britain 1 to 4, in Shetland 1 to 3.3, in the Faroe Islands 1 to $2\frac{1}{4}$. There is thus an increase in the proportion of Monocotyledons in passing from the Canaries, Lat. 28°, to Madeira, Lat. 32°, the Azores, Lat. 38°, Great Britain, Lat. 50° 57′, Shetland, Lat. 60°, and Faroe, Lat. 62°. In the arctic regions, on the other hand, Hooker remarks, the proportion seems to be inverted. In central and southern Europe, the proportion of Monocotyledons to Dicotyledons, which is 1 to 4 in the plains, decreases with the elevation on dry mountain slopes, till, at the height of 8526 feet, it is 1 to 7. Moist mountain slopes favour Monocotyledons, the proportion on them being as 1 to 3. In South Australia, Monocotyledons are to Dicotyledons as 1 to 4, varying, however, according to latitude, the mean being between the vegetation of New South Wales and Van Diemen's Land. In Western Australia, the proportion is 2 to 9. while the Acotyledons are to Dicotyledons as 1 to 6.

In the low plains of the great continents within the tropics, Ferns are to Phanerogamous plants as 1 to 20; on the mountainous parts of the great continents, in the same latitudes, as 1 to 8 or 1 to 6; in Congo as 1 to 27; in New Holland as 1 to 26. In small islands, dispersed over a wide ocean, the proportion of Ferns increases; thus, while in Jamaica the proportion is 1 to 8, in Otaheite it is 1 to 4, and in St Helena and Ascension nearly 1 to 2. In the temperate zone, Humboldt gives the proportion of Ferns to Phanerogamous plants as 1 to 70. In colder regions the proportion increases, that is to say, Ferns decrease more slowly in number than Phanerogamous plants. The proportion is least in the middle temperate zone, and it increases both towards the equator and towards the poles; at the same time, it must be remarked, that Ferns reach their absolute maximum in the torrid zone, and their absolute minimum in the arctic zone.

Taking other natural orders, we find that Juncaceæ, Cyperaceæ, and Gramineæ increase in proportion to all the

Botany. Phanerogamous species as the latitude becomes higher; thus, in the torrid zone, the proportion is 1 to 11, in the temperate zone 1 to 8, and in the arctic zone 1 to 4. Cinchonaceæ, Leguminosæ, Euphorbiaceæ, and Malvaceæ, increase in their proportion to Phanerogamæ as we approach the equator. The natural orders Cruciferæ, Umbelliferæ, and Compositæ, have their highest quotients in the temperate zone. Piperaceæ are plants of the hottest regions; Papaveraceæ are chiefly European; Chinchonaceæ, within the tropics, form 1-29th of the flowering plants; Scrophulariaceæ, in the middle of Europe, are to Phanerogams as 1 to 26, in North America as 1 to 36. Labiate have their maximum between 40° and 50° N. Lat. Boraginaceæ are chiefly confined to the temperate regions, while Primulaceæ and Gentianaceæ abound in colder zones.

The proportion of species as well as of genera, belonging to the same natural order, varies in different countries. Of Ranunculaceæ 1-5th of the species are European, 1-7th North American, 1-17th South American, and 1-25th Indian; of Papaveraceæ nearly 2-3ds are European; of Cruciferæ 205 species, according to De Candolle, are found in the frigid zone of the northern hemisphere, 30 in the tropics (chiefly on mountains), 548 in the northern temperate zone, and 86 in the southern temperate zone. De Candolle states that about 1600 species of Leguminosæ are found in the equinoctial zone, about 1300 to the north of the tropics, and about 500 to the south. Of 9030 Compositæ mentioned by authors, 3590 are found in America, 2224 in Africa, 1827 in Asia, 1042 in Europe, and 347 in the South Sea Islands. Of 2500 species of Euphorbiaceæ 3-8ths are found in equinoctial America, 1-8th in tropical Africa, 1-6th in India, 50 species in America, and 120 in Europe. Lomler calculates that 165 Coniferæ exist in the northern and 51 in the southern hemispheres. There are, according to him, 22 in Europe, 87 in Asia, 16 in Africa, 83 in America, and 35 in Australia.

VI.—ZONES OF VEGETATION AS REGARDS LATITUDE.

We have already seen that the vegetation varies according to latitude, and that we may trace a series of changes in the flora from the equator to the poles. Meyen proposes to mark out round the world a number of climacteric zones or belts, and to connect with the fact of these zones of climate the peculiarities of the vegetation of the belts. Meyen's plan is not quite correct, because he has made his belts to correspond with the parallels of latitude, and has asserted that between such and such parallels a certain form of vegetation would be found all over the world. The boundary lines of the zones, in order to be accurate, should be undulatory; they should correspond with the isotherm of the particular month in which there is the greatest development of vegetable life. Such undulatory zones, in which the plants present a certain resemblance to each other by sea and land, are denominated by Forbes Homoizoic.

As regards vegetation, Meyen divides the Torrid zone into—1. The equatorial, extending 15° on both sides of the equator, having a mean annual temperature of 78°8 to 82°4 F. 2. The tropical, reaching from the 15th degree on each side of the equator to Lat. 23°, having a mean annual temperature of 73° 4 to 78° 8, a summer heat of 80° 6 to 86°, and a winter temperature in the eastern coast countries of 59°. The Temperate zone is divided by Meyen into-1. The sub-tropical, from the tropics to 34° Lat., with a mean annual temperature of 62° 6 to 71° 6, and a summer temperature of 73° 4 to 82° 4. 2. The warmer temperate zone, from Lat. 34° to 45°, having a mean annual temperature of 53°6 to 62° 6, the summer temperature, in North America 77°, in Europe 68° to 75° 2, and in eastern Asia 82° 4; the winter temperature in America being 32°-54 to 44°-6, in VOL. V.

colder temperate zone, between the parallels of 45° and 58°, the temperature of the year 42°8 to 53°6; the minimum summer temperature on the west coast 56°:31, in the interior of the continent 68°; the minimum winter temperature in the interior of Europe 14°. 4. The sub-arctic zone, from Lat. 58° to the polar circle in Lat. 66°·32, mean annual temperature 39°·2 to 42°·8; temperature of summer in America 66°·2, in the Old World 60°·8 to 68°; winter temperature of America 14°, of western Europe 24°·8, and of the interior of Russia 10°·4 to 14°. The Frigid zone is divided into—1. The arctic, from the polar circle to Lat 72°, mean annual temperature being 28°.4 to 32°, and towards the eastern continental regions much lower. 2. The polar, beyond 72° of latitude; mean annual temperature in the Old World 16°.7, in the New World 1°.4; the summer of the former 38°.3, of the latter 37°.4; winter of the former $-2^{\circ}.2$, of the latter $-28^{\circ}.$

Equatorial Zone.—This embraces central Africa, including the Guinea coast and Abyssinia, &c., Ceylon, the southernmost part of Hindustan, Malaya, Cochin-China, Sumatra, Borneo, Java, New Guinea, islands in the eastern seas, the northernmost part of Australia, the northern part of South America, including Columbia, Peru, the Guianas, and part of Brazil. The vegetable forms characteristic of this zone are Palmæ, Musaceæ, arborescent Grasses, Zingiberaceæ, Marantaceæ, Orchidaceæ, and Lianas. Species of Bombax and Ficus occur here, with gigantic trees such as the Baobab, species of Swietenia, Hymenæa, and Cæsalpinia. The orders Malpighiaceæ, Anonaceæ, Anacardiaceæ, Lecythidaceæ, Sapindaceæ, Artocarpaceæ, Sterculiaceæ, Ebenaceæ, Meliaceæ, Lauraceæ, and Rafflesiaceæ, are also well represented in this zone.

Tropical Zone.—This includes parts of Bolivia, Brazil. and Paraguay in South America, the majority of the West India Islands, Yucatan, Guatemala, and part of Mexico, Nubia and Senegambia in Africa, Madagascar, Mauritius, and North Australia, part of China and India, Burmah, and the south of Arabia. As Palms and Bananas may be said to characterize the equatorial zone, so may arborescent Ferns and species of Ficus be said to predominate in the tropical zone. Besides many equatorial forms, we meet here with plants belonging to the orders Piperaceæ, Melastomaceæ, and Convolvulaceæ.

Sub-tropical Zone.—This embraces the north of Africa, including the Great Desert, Morocco, Barbary, Algiers, Tunis, Tripoli, and Egypt; in Asia, Palestine, Syria, north of Arabia, Persia, Cabul, Beloochistan, Thibet, the north of India, and China; the southern part of Australia; south Africa; Paraguay, La Plata, Chili, and Banda, in South America; the Bahamas, Bermuda, Mexico, Texas, the Southern States, and California, in North America. In this zone vegetation is green throughout all the year, like the forests of the damp regions of the torrid zone. It is called the region of Myrtaceæ and Lauraceæ. Certain Palm forms are seen, such as Phœnix dactylifera in Egypt (represented in India by Phœnix sylvestris and P. humilis), Hyphæne thebaica, Chamærops Palmetto. In this zone we meet with succulent Crassulaceæ, Mesembryanthemaceæ, Cactaceæ, and arborescent Euphorbiaceæ, plants belonging to the orders Ternströmiaceæ and Magnoliaceæ; and in the southern hemisphere especially Proteaceæ, Epacridaceæ, and Ericaceæ, along with species of Zamia and Diosma.

Warmer Temperate Zone.—In Europe this includes the southern flora as far as the Pyrenees, the mountains in the south of France, and those in the north of Greece. Asia Minor, the country between the Black Sea and the Caspian, the north of China, and Japan lie in this zone. It has been called the region of evergreen trees. Chamærops humilis represents the Palms, Erica arborea the Heaths, Laurus nobilis the Laurels, and Myrtus communis the Myrtles, in Europe 34° 7 to 50°, and in eastern Asia 26° 6. 3. The this zone, in which there are many sub-tropical forms. Spe-

Botany. cies of Cistus, Vaccinium, Smilax, Eucalyptus, and Mela leuca are met with, as well as many forms of Compositæ, also Figs, Oranges, Pomegranates, and the Vine.

Colder Temperate Zone.-In the northern hemisphere the characteristic forms of the vegetation of this zone are seen in England, the north of France, and Germany. The forests consist of Dicotyledonous trees and especially Coniferæ; the successful cultivation of Wheat scarcely extends beyond the limits of this zone. Heaths, covered with Calluna vulgaris, add a feature in the physiognomy of this zone. The floras of Tierra del Fuego, the Straits of Magalhaens, the Falkland Islands, and Kerguelen's Land, are also included in this zone. We meet with Drymis Winteri, Fagus antarctica, and F. Forsteri, Dactylis cæspitosa, Pringlea antiscorbutica, and many other interesting forms described by Dr Hooker in his Flora Antarctica.

Sub-arctic Zone.—This zone is of less extent than the preceding, and in the interior of Asia it is perhaps not so easily distinguishable from it as it is in Europe. In the northern hemisphere it is the zone of Firs and Willows. In the southern hemisphere it embraces a few barren islands. The northern parts of Siberia and Norway, the Faroe Islands, and Iceland, belong to this zone. In the Faroe Islands Barley does not always ripen, but the Turnip and Potato succeed. The Amentiferæ in them, as well as in Iceland, do not become trees. Grasses, Calluna vulgaris, and Juniperus communis, form features in the physiognomy of Iceland, and Alpine species come down nearly to the sea level. In Siberia, forests of Pinus Cembra, Larch, Spruce, Poplar, and Birch occur.

Arctic Zone.—In this zone the Birch predominates, and along with it are seen Pinus sylvestris and Abies excelsa. The Birch reaches nearly to North Cape, and Firs extend to 69° or 70°. Grasses are also found, and numerous Lichens and Mosses. At Hammerfest, in Lat. 71°, Potatoes, Turnips, Carrots, and Cabbage succeed. Species of Rhododendron, Andromeda, and Azalea occur in the American arctic zone.

Polar Zone.—In this zone there are no trees nor bushes, and no cultivation of plants for food. Species of Saxifrage, Dryas, Papaver, Ranunculus, Cardamine, Cochlearia, Pedicularis, Silene, Potentilla, Salix, Juncus, Eriophorum, Parrya, Platypetalum, Phippsia, Dupontia, and a few others, are found in this inhospitable belt. In Melville Island there are 67 species of flowering plants, in Spitzbergen 45. In cold zones we find more genera and fewer species than in warmer regions.

VII.—ZONES OF VEGETATION AS REGARDS ALTITUDE.

The vertical range of vegetation has been divided into zones similar to those of the horizontal range. The relation of plants to such zones of elevation is called Hypsometrical. As we ascend from the plain to the top of a mountain we pass through different belts of vegetation, the extent and variety of which differ in different countries. When Tournefort ascended Mount Ararat he was struck with the circumstance, that, as he left the low ground at the base of the mountain, he passed through a series of belts, which reminded him of the countries he had passed through in travelling from the south to the north of Europe. At the base the flora was that of the west of Asia; as he ascended higher he reached the flora of the countries on the north of the Mediterranean, then that of northern Europe, and when he reached the summit he found the Lapland plants. Humboldt found that on all mountains there occurs such a representation of different floras, and that particular alpine forms are found almost over the whole world at a particular elevation. In describing the South American alpine flora, he says-"In the burning plains scarce raised above the level of the Southern Ocean, we find Musaceæ, Cycadaceæ, and Palmæ, in the greatest luxuriance; after them, shaded by the lofty

sides of the valleys in the Andes, arborescent Ferns; next Botany. in succession, bedewed by cool misty clouds, Cinchonas appear. When lofty trees cease, we come to Aralias, Thibaudias, and Myrtle-leaved Andromedas; these are succeeded by Bejarias abounding in resin, and forming a purple belt around the mountains. In the stormy region of the Paramos, the more lofty plants and showy flowering herbs disappear, and are succeeded by large meadows covered with Grasses on which the Llama feeds. We now reach the bare trachytic rocks, on which the lowest tribes of plants flourish. Parmelias, Lecideas, and Leprarias, with their many-coloured thalli and fructification, form the flora of this inhospitable zone. Patches of recently fallen snow now begin to cover the last efforts of vegetable life, and then the line of eternal snow begins."

Madden and Strachey give the following account of the Himalayan vegetation, proceeding from the plains of India through Kemaon to Thibet:- "Ascending, we find forms of temperate climates gradually introduced above 3000 feet, as seen in species of Pinus, Rosa, Rubus, Quercus, Berberis, Primula, &c. At 5000 feet the arborcous vegetation of the plains is altogether superseded by such trees as Oaks, Rhododendron, Andromeda, Cypress, and Pine. The first ridge crossed ascends to a height of 8700 feet in a distance of not more than 10 or 12 miles from the termination of the plains. The European character of the vegetation is here thoroughly established, and although specific identities are comparatively rare, the representative forms are most abundant. From 7000 to 11,000 feet, the region of the alpine forest, the trees most common are Oak, Horse-chestnut, Elm, Maple, Pine, Yew, Hazel growing to a large tree, and many others. At about 11,500 feet the forest ends, Picea Webbiana and Betula Bhojpatra being usually the last trees. Shrubs continue in abundance for about 1000 feet more; and about 12,000 feet the vegetation becomes almost entirely herbaceous. On this southern face of the mountains the snow-line is probably at about an elevation of 15,500 feet. The highest dicotyledonous plant noticed was at about 17,500 feet, probably a species of Echinospermum. An Urtica also is common at these heights. The snow-line here recedes to 18,500 or 19,000 feet. In Thibet itself the vegetation is scanty in the extreme, consisting chiefly of Caragana, species of Artemisia, Astragalus, Potentilla, a few Gramineæ, &c. The cultivation of Barley extends to 14,000 feet. Turnips and radishes on rare occasions are cultivated at nearly 16,000 feet. Vegetation ends at about 17,500 feet, scanty pasturage being found in favoured localities at this elevation; and the highest flowering plants are Corydalis, Cruciferæ, Nepeta, Sedum, and a few others."

If we examine the vegetation of the mountains of Europe we shall find a series of similar changes. In the regions of the plains and lower hills of the Alps, extending to 1700 feet, the Vine grows; to this succeeds the zone of Chestnuts, which extends to 2500 feet; the zone of the Beech, and of the higher dicotyledonous trees, reaches from 2500 to 4000 feet; we then come to the sub-alpine region, the zone of Coniferæ, extending to about 6000 feet, in which are found the Scotch Fir, the Spruce, the Larch, and the Siberian Pine, along with certain sub-alpine forms of herbaceous plants; next comes the alpine region, or the zone of shrubs, extending to 7000 feet, characterized by Rhododendron hirsutum, and R. ferrugineum, which represent the Bejarias of the Andes; finally, we reach the subnival region, extending to 8500 feet, and comprehending the part between the limits of shrubs and the snow-line, where we meet with numerous species of Ranunculus, Draba, Saxifraga, Gentiana, Primula, and Poa, besides other genera belonging to Ranunculaceæ, Cruciferæ, Caryophyllaceæ, Leguminosæ, Compositæ, Gramineæ, Lichenes, and Musci. On some of the Alps we find flowering plants reaching to the height of between 10,000 and 11,000 feet or more. Schlagintweit

Botany.

Rotany. found, on the central and southern Alps, at from 10,650 to 11,700 feet, Androsace glacialis, A. helvetica, Cerastium latifolium, Cherleria seloides, Chrysanthemum alpinum, Gentiana bavarica, Ranunculus glacialis, Saxifraga bryoides, S. oppositifolia, and Silene acaulis. The extreme limit of Mosses in the Alps is in general little above that of Phanerogamous plants. The last Lichens are to be found on the highest summits of the Alps, attached to projecting rocks, without any limitation of height.

On the Pyrenees the following zones are observed:-The zone of Vine and Maize cultivation, and of the Chestnut woods. 2. A zone extending from the limit of the Vine to about 4200 feet, at which limit the cultivation of Rye ceases; here we meet with Buxus sempervirens, Saxifraga Geum, Erinus alpinus, Arnica montana, &c. 3. From the limit of the cultivation of esculent vegetables at 4200 feet, to the zone of the Spruce Fir. 4. From the limit of the Spruce Fir zone at 6000 to 7200 feet, characterized by the presence of the Scotch Fir. 5. From 7200 to 8400 feet, is an alpine zone, characterized by the dwarf Juniper, Draba aizoides, Saxifraga bryoides, Soldanella alpina, Juncus trifidus, &c. 6. A zone above 8400 feet, exhibits a few alpine species, as Ranunculus glacialis, Draba nivalis, Stellaria cerastoides, Androsace alpina, and Saxifraga gröen-

There are thus in lofty mountain districts evident belts of vegetation. At the lower part is the region of Lowland Cultivation, where the ordinary cultivated plants of the country thrive. In cold regions this is very limited, while in warm regions it is extended. To this region succeeds that of Trees. In high northern latitudes, as at 70°, it reaches to between 700 and 800 feet; on Ætna to 6200; on the Andes to 10,800, and it is marked by Escallonia myrtilloides, Aralia avicennifolia, and Drymis Winteri; on the mountains of Mexico to 12,000 feet, and is marked by Pinus Montezumæ; on the south side of the Himalaya to 11,500, and on the north side to 14,000. On the Pyrenees its limits are marked at about 7000 feet by Pinus uncinata, on the Alps at about 6000 feet by Pinus Picea, on the Caucasian mountains at 6700 feet, and in Lapland at about 1500 feet by the Birch. Next in order comes the Shrubby region, the limits of which in Europe are marked by Rhododendrons, which cease on the Alps of 7400 feet, and on the Pyrenees at 8332 feet; on the Andes it is limited by Bejarias and shrubby Compositæ, at a height of 13,420 feet; on the south side of the Himalaya, by species of Juniper, Willow, and Ribes, at an elevation of 11,500 feet. In Lapland, species of Willow and Vaccinium, with the dwarf Birch, reach 3300 feet. The next region is that of Grasses, which on the Andes and the Himalaya extends to between 14,000 and 15,000 feet. Finally, we come to the region of Cryptogamic plants, which extend to the snow-line, Lichens being the last plants met with.

In contrasting the zones of altitude with those of latitude, Meyen gives the following regions of alpine vegetation:— The region of Palms and Bananas (equatorial) extending from the sea level to 1900 feet; the region of Tree-ferns and of Figs (tropical) 1900 to 3800 feet; the region of Myrtles and Laurels (sub-tropical) 3800 to 5700 feet; region of evergreen dicotyledonous trees (warm temperate) 5700 to 7600 feet; region of deciduous dicotyledonous trees (cold temperate) 7600 to 9500 feet; region of Abietineæ (sub-arctic) 9500 to 11,400 feet; region of Rhododendrons (arctic) 11,400 to 13,300 feet; region of alpine plants (polar) 13,300 to 15,200.

VIII.—SCHOUW'S PHYTO-GEOGRAPHIC REGIONS.

In dividing the globe into Phyto-geographic regions, Schouw takes into account the nature of the flora in regard to species, genera, and orders, irrespective of the effects

they may produce on the physiognomy of the country. In constituting a botanical region, he lays down the principle that at least one-half of the species and one-fourth of the genera should be peculiar to it, and that individual orders should either be peculiar to it or reach their maximum in He constitutes 25 Regions:—1. Region of Saxifrages and Mosses. 2. Region of Umbelliferæ and Cruciferæ. 3. Region of Labiatæ and Caryophyllaceæ. 4. Region of Asters and Solidagos. 5. Region of Magnolias. 6. Region of Camellias and Teas. 7. Region of Zingiberaceæ. 8. Himalayan Alps. 9. Asiatic Islands. 10. Mountains of Java. 11. Islands of the Pacific. 12. Region of Balsam trees. 13. The Desert Region. 14. Region of Tropical Africa. 15. Region of Cactuses and Peppers. 16. Mountains of Mexico. 17. Region of the Medicinal Barks. 18. Region of Calceolarias and Escallonias. 19. West Indian Region. 20. Region of Palms and Melastomas. 21. Region of Tree Compositæ. 22. Antarctic Region. 23. Region of Mesembryanthemums and Stapelias. 24. Region of Epacridaceæ and Eucalypti. 25. Region of New Zealand.

REGION I.—The region of Saxifragaceæ and Musci or the Alpine Arctic Flora.—This embraces the north polar lands from the limits of ice to the zone of trees, or what is called the Arctic flora, in which Mosses, Lichens, and Carices abound; and the upper parts of the mountains of Europe and northern Asia from the snow-line down to the arborescent belt, or the Alpine flora, in which Primulaceæ and Saxifragaceæ are prevalent. The mean temperature of the arctic division is 41° to 66°, that of the Alpine districts is 36° to 47°. In this region there is no cultivation.

REGION II.—The region of Umbelliferæ and Cruciferæ.— This extends over northern Europe and Asia from the southern limit of the last region to the Pyrenees, the Alps the Balkan mountains, the Caucasus, and the Altai; the mean temperature being 36° to 57°. It is distinguished by the presence of Umbelliferous and Cruciferous plants. Coniferæ, Amentiferæ, Ranunculacæ, Rosaceæ, and Fungi are abundant.

REGION III.—The region of Labiatæ and Caryophyllaceæ or the Mediterrannean Flora.—This comprises the countries of the Mediterranean Sea, Spain, the south of France, Italy, Greece, Asia Minor, Egypt, the whole of northern Africa to the Sahara and the great Atlas chain, the Canaries, and Madeira. The upper mountain regions belong to Schouw's first region, and the middle to his second. The mean temperature is 54° to 72°. The region is characterized by the prevalence of plants belonging to the Labiate and Clovewort orders. Species of Compositæ, Galiaceæ, and Boraginaceæ also abound, and there is an increase in the plants belonging to the orders Leguminosæ, Malvaceæ, Solanaceæ, Urticaceæ, and Euphorbiaceæ.

REGION IV .- The region of Asters and Solidagos --This extends over the northern part of North America from the limits of the first region to the parallel of 36° north. Besides the number of species of Aster and Solidago (belonging to Compositæ), this region is marked by a great variety of Oaks and Firs, by numerous species of Vaccinium, by the smallness of the number of Cruciferæ, Umbelliferæ, Cinchonaceæ, Cynarocephalæ, and by the absence of the genus Erica. The mean temperature is 54° to 72°. The Californian and Oregon districts, to the west of North America, constitute a region not yet fully explored. Many showy Polemoniaceæ and interesting Coniferæ are found here; also Eschscholtzia californica.

REGION V.—The region of Magnolias.—This embraces the southern part of North America between the parallels of 30° and 36°. Here we meet with numerous tropical forms, ! as Zingiberaceæ, Cycadaceæ, Anonaceæ, Sapindaceæ, Melastomaceæ, and Cactaceæ. Mean temperature 59° to 72°.

REGION VI.—The region of Ternströmiaceæ and Celastraceæ, or the Japanese region.—This extends between the parallels of 30° and 40° N. Lat., and embraces Japan, the

Botany. north of China, and Chinese Tartary, constituting the eastern temperate parts of the Old World. The flora seems to be intermediate between that of the Old and the New World. The vegetation is more tropical than European, for we meet with Zingiberaceæ, Musaceæ, Palmæ, Cycadaceæ, Anonaceæ. The mean temperature is 54° to 68°.

REGION VII.—The region of Zingiberaceæ, or the Indian Flora.—This embraces India, the island of Ceylon, and the south-eastern peninsula, to the height of 4500 to 5500 feet above the level of the sea. There are here numerous specimens belonging to the Ginger order as well as to Leguminosæ, Cucurbitaceæ, and Tiliaceæ. The Coco-nut, Mangosteen, Turmeric, Cinnamon, Cotton, Indigo, Clove, and Pepper, are abundant. Mean temperature 65° 75 to 81° 50. The south of China and Cochin-China may be considered as a distinct region. It partly resembles that of India,

but contains many peculiar plants.

Region VIII.—The Emodic region.—This embraces the Alpine region of India south of the ridge of the Himalaya, including Sirmore, Gurwal, Kemaon, Nepal, and Bhotan, to a height of from 4500 to 10,700 feet above the level of the sea. Some European species are met with in these high districts. Cedrus Deodara, Pinus excelsa, P. longifolia, Picea Webbiana, and other Coniferæ, along with Chamærops Khasyana, species of Oak, Dammar, Rhododendron, Berberis, Primula, &c., also occur. In the lower parts of the region tropical plants grow. The mean temperature is 37° to 66°.

REGION IX.—The region of the Asiatic Islands.—This comprises the mountainous districts of the islands between the south-eastern peninsula and Australia, to a height of 5500 feet above the level of the sea. Myristica moschata, Dryabalanops Camphora, and Dammara orientalis, grow in this region. Much of it is still unexplored. The mean temperature is 66° to 84°.

REGION X .- The region of Upper Java. - This comprehends the districts of the island of Java, and probably also of the numerous islands of the Asiatic archipelago, having an absolute elevation of 5500 feet above the level of the sea. Little is known in regard to the vegetation.

REGION XI.—The Polynesian region.—This comprises all the islands of the Pacific Ocean within the tropics. Among the plants of this region may be mentioned Artocarpus incisa, Tacca pinnatifida, Cocos nucifera, Lodoicea seychellarum, Jambosa malaccensis, and many species of Arum, Dioscorea, Musa, and Ficus. The genera Dissochæta, Orophea, Pterisanthes, Arthrophyllum, and Visenia, occur in this region. The mean temperature is 72° to 82°.

REGION XII.—Theregion of Amyridaceæ.—This includes the south-western part of the highlands of Arabia. In the flora are many trees yielding gum and balsamic resins, such as species of Mimosa, Acacia, Balsamodendron, and Amyris. Coffee and the Sensitive-plant occur here.

REGION XIII.—The Desert region.—This comprehends northern Africa, to the south of the Atlas Mountains, between Lat. 15° and 30° N., and the northern part of Arabia. Phœnix dactylifera and Hyphæne thebaica are characteristic plants of the region. The mean temperature is 72° to 86°.

REGION XIV.—The region of tropical Africa.—This comprises that part of Africa which lies between 15° N. Lat. and the tropic of Capricorn, or, more correctly, between the northern and southern limits of periodical rains, with the exception of Abyssinia and the unknown countries of the interior. On the western part of this region, Elais guineensis the Palm-oil plant, and Adansonia digitata the Baobab, grow. On the coast of Guinea and Congo, the flora is intermediate between that of America and Asia, but chiefly resembling the latter. Species of Sorghum, Sterculia acuminata the Kola-nut, and the Poison-hean of Calabar, belong to this region. The mean temperature of the region is 72° to 86°.

REGION XV.—The region of Cactaceæ and Piperaceæ.— Botany. This embraces Mexico, Guatemala, the Isthmus of Panama, and South America as far as the river Amazon, and to an elevation of 5500 feet above the level of the sea, between Lat. 30° N. and the equator. Guiana, New Grenada, and certain parts of Peru are included. Cactuses and Peppers abound in this region.

REGION XVI. The region of the Mexican Highlands. This embraces the districts of Mexico which have an elevation of more than 5500 feet above the level of the sea. Some important Coniferæ are met with here, such as Pinus religiosa, P. apulcensis, P. Hartwegii, P. Montezume, and Taxodium distichum. The mean temperature is 64° to 78°.

REGION XVII.—The region of Cinchonas or medicinal Bark-trees. This comprehends the Cordilleras of South America, between the parallels of 5° N. Lat. and 20° S. Lat., at an elevation of 5000 to 9600 feet. The mean temperature is 59° to 68°. In the lower part of the region Coffee and Maize are cultivated, and in the higher regions the European grains and fruits, along with the Potato and Ceroxylon Andicola is also the Chenopodium Quinoa. found in this region of the Andes.

REGION XVIII.—The region of Escallonias and Calceolarias.—This comprises the highest districts in South America above the upper limit of Cinchonas. The mean temperature varies from 59° to 84°. Besides Escallonias and Calceolarias, we meet with many alpine plants.

REGION XIX.—The West Indian Region.—This region comprehends the West India Islands, the flora of which may be said to be intermediate between that of Mexico and the northern parts of South America. Ferns and Orchids prevail. Mean temperature 59° to 78°.

REGION XX.—Region of Palms and Melastomas.—This comprises that part of South America to the east of the Andes which lies between the equator and the tropic of Capricorn. Mean temperature 59° to 82°. Here we have the luxuriant Brazilian flora. Palms, Melastomaceæ, Myrtaceæ, Tree-ferns, and Crotons, form the thick underwood, and beneath these, delicate herbaceous Ferns; Dorstenias, Heliconias, with a few tall Grasses, are found in the open

REGION XXI.—The region of arborescent Composites. This embraces South America on both sides of the Andes from the tropic of Capricorn to Lat. 40. S. In it are included the southern part of Brazil, La Plata, and Chili. Mean temperature 59° to 75°. In Chili there are many genera which also are represented in Australia and at the Cape of Good Hope. Araucaria imbricata, the Banksian or Chili pine, is a hardy Conifer of this district, extending on the Chilian Andes from 37° to 40° S. Lat.

REGION XXII.—The Antarctic region.—This embraces the southern part of America, the Straits of Magalhaens, Tierra del Fuego or Fuegia, the Falkland Islands, and others more to the south. Mean temperature 41° to 46°. Many mountainous plants are found in this region. The vegetable forms of the north temperate and arctic zones prevail. Species of Saxifraga, Gentiana, Arbutus, and Primula, with many other European genera, abound. In Fuegia the Evergreen Beech, Fagus Forsteri, which never sheds its coriaceous foliage, is a very prevalent tree, also the Deciduous Beech, Fagus antarctica, the leaves of which change colour and fall, and Drymis Winteri. In the Falkland Islands there are about 120 flowering plants, consisting chiefly of those found on the mountains of Fuegia, and on the arid coast and plains of Patagonia.

REGION XXIII.—The region of Mesembryanthemums and Stapelias.—This embraces southern Africa from the the tropic of Capricorn to the Cape Coast. Mean temperature 55° to 73°. Besides species of Mesembryanthemum and Stapelia there are a prodigious number of species of Erica. The latter genus attains its maximum here. We

Botany. also meet with plants belonging to the orders Iridaceae Bruniaceæ, and Selaginaceæ.

REGION XXIV.—The region of Epacridaceæ and Eu calypti.—This comprehends Australia beyond the tropics with the island of Tasmania or Van Diemen's Land. Mean temperature 52° to 72°. The number of known Australian plants amounts to about 7000 or 8000. The flora of Australia approaches in its tropical portion to the plants of India, and in its extra-tropical portion to those of South Africa. The flora may be divided into a western, southern, eastern, and Tasmanian flora. In the western districts Leguminosæ and Proteaceæ predominate, forming one-fourth of the entire vegetation; Ferns and Grasses are rare. In the southern flora, Compositæ and Leguminosæ abound along with Salsolas, Myoporaceæ, Halorageaceæ, Caryophyllaceæ, and Cruciferæ. The genus Mesembryanthemum is here seen as a connecting link with the South African flora; Nitraria with the Siberian, and Crantzia with the North American flora. In the eastern flora Proteaceæ and Epacridaceæ are found, with fewer Composite than in the south, and a larger number of Ferns and Grasses than in the western district. In South Australia Compositæ form 1-8th of the whole vegetation; Compositæ and Leguminosæ form together one-third of the whole of the Dicotyledons.

REGION XXV.—The region of New Zealand.—This includes the islands of New Zealand and those which are adjacent. Between Lat. 34° and 36° S. the mean temperature is 61° to 63°. Here we meet with Phormium tenax the New Zealand Flax-plant, Corypha australis the southern Palm, abundance of Ferns, many of them arborescent, species of Dracæna, many Myrtaceæ, and some peculiar Coniferæ. The known flora of New Zealand amounts to about 1900 or 2000 species, of which 730 are flowering plants, thus making Phanerogams to Cryptogams nearly as 2 to 3. Among the orders to which the endemic species belong may be noticed Coniferæ, Scrophulariaceæ, Epacridaceæ, Compositæ, Araliaceæ, Umbelliferæ, Myrtaceæ, and The flora of the Auckland group and Ranunculaceæ. of Campbell's Island may be considered as a continuation of that of New Zealand, differing only in being more typical of the antarctic regions.

IX.-ZONES OF MARINE VEGETATION.

The ocean, as well as the land, possesses its vegetable forms, which are of a peculiar kind, and exist under different conditions of pressure, of surrounding medium, and of light. Some seaweeds, Harvey remarks, are cosmopolitan or pelagic, as species of Ulva and Enteromorpha, which are equally abundant in high northern and southern latitudes, as they are under the equator, and in temperate regions. Codium tomentosum, Ceramium rubrum, C. diaphanum, species of Ectocarpus, and several Confervæ, have a range nearly as wide. Plocamium coccineum and Gelidium corneum are common to the Atlantic and Pacific oceans; Rhodymenia palmata, the common Dulse of Britain, is found at the Falkland Islands and Tasmania. cus tuberculatus extends from Ireland to the Cape of Good Hope; Fucus vesiculosus occurs on the north-west coasts of America, and on the shores of Europe; while Desmarestia ligulata is found in the north Atlantic and Pacific oceans, as well as at the Cape of Good Hope and Cape Horn.

In general, however, Sea-weeds are more or less limited in their distribution, so that different marine floras exist in various parts of the ocean. The northern ocean, from the pole to the 40th degree, the sea of the Antilles, the eastern coasts of South America, those of New Holland, the Indian Archipelago, the Mediterranean, the Red Sea, the Chinese and Japanese Seas, all present so many large marine regions, each of which possesses a peculiar vegetation. The degree of exposure to light, and the greater or less motion of the

waves, are very important in the distribution of Algæ. The Botany. intervention of great depths of the ocean has a similar influence on sea-plants as high mountains have on landplants. Laminariæ are confined to the colder regions of the sea; Sargassa only vegetate where the mean temperature is considerable. Under the influence of the Gulfstream, Sargassum is found along the east coast of America, as far as Lat. 44°; and the cold south polar current influences the marine vegetation of the coasts of Chili and Peru, where we meet with species of Lessonia, Macrocystis, D'Urvillæa, and Iridæa, which are characteristic of the antarctic flora. Melanospermeæ, according to Harvey, increase as we approach the tropics, where the maximum of the species, though, perhaps, not of individuals, is found; Rhodospermeæ chiefly abound in the temperate zone; while Chlorospermez form the majority of the vegetation of the polar seas, and are particularly abundant in the colder temperate zone. The green colour is characteristic of those Algæ which grow either in fresh water or in the shallower parts of the sea; the olive-coloured Algæ are most abundant between the tide-marks; while the red-coloured species occur chiefly in the deeper and darker parts of the sea.

As regards perpendicular direction, Forbes remarks, that one great marine zone lies between high and low watermarks, and varies in species according to the kind of coast, but exhibits similar phenomena throughout the northern hemisphere. A second zone begins at low water-mark, and extends to a depth of 7 to 15 fathoms. This is the region of the larger Laminarias and other Fuci. Marine vegetation, including the lower forms, extends to about 50 fathoms in the British seas, to 70, 80, or 100, in the Mediterranean and the Ægean Sea. Ordinary Algæ, however, seem scarcely to exist below 50 fathoms. Diatomaceæ exist in the deep abysses of the ocean, and Nullipora and Corallines increase as other Algæ diminish, until they characterize a zone of depth where they form the whole obvious vegetation.

The distribution varies also in a latitudinal or horizontal direction. Chorda Filum lies in beds of 15 to 20 miles in length, and only about 600 feet in breadth, in the North Sea and the British Channel. Sargassum bacciferum constitutes the Gulf-weed, which has been noticed by all who have crossed the Atlantic. The Sargasso Sea occupies the eddy or whirl caused by the revolution of the current in the Atlantic, and occupies a space of 260,000 square miles. The most remarkable of marine plants, both for their size and the extent of their range, are the Macrocystis pyrifera and the Laminaria radiata. Immense masses of the Macrocystis, like green meadows, are found in every latitude. It ranges from the antarctic to the arctic circle through 120 degrees of latitude. The tribe Fucoideæ abounds towards the poles, and there the plants attain their greatest bulk, diminishing rapidly towards the equator and ceasing some degrees from the Line itself. Cystoseireæ represent the Fucoideæ in the higher latitudes of the southern hemisphere. Laminarias abound in the antarctic ocean and northwards to the Cape of Good Hope. The red, green, and purple Lavers of the British seas are found at the Falkland Islands. Lessonia, with a stem 10 feet long and 12 inches in circumference, and its frond 2-3 feet long and about 3 inches broad, is found in immense masses off the Patagonian regions. D'Urvillæa utilis is another large antarctic Seaweed, which, along with Lessonias, is often found at the Falkland Islands, formed by the surf into enormous vegetable cables, several hundred feet long, and thicker than the human body.

X.—DISTRIBUTION OF PLANTS IN BRITAIN.

The climate of Britain is warmer than that of other places in the same parallel of latitude. Its most striking feature is the absence of extremes, either as regards cold or heat. It is, generally speaking, mild and damp. While the winters are mild, the heat of the three summer months, June, July,

Botany. and August, in which the growth and ripening of crops take place, is by no means great, being very little above that due to the latitude. The eastern coasts of Britain partake more of the continental climate, while on the western the climate is of an insular and equable character. The mean temperature varies from 46° to 52° F. Some of the mountains rise to the height of 4400 feet, and there is a fall of 1° of the thermometer of every 240 or 250 feet of ascent. The number of Phanerogamous species of plants amounts to about

1600, while the Cryptogamous are about 2800.

Taking a general view of the distribution of British Flowering Plants and Ferns (excluding the Hibernian and Sarnian species), Watson recognises the following types: -1. British type-species widely and generally spread over Britain, and forming probably 2-5ths of the British species, such as Alnus glutinosa, Betula alba, Corylus Avellana, Salix capræa, Rosa canina, Lonicera Periclymenum, Hedera Helix, Sarothamnus scoparius, Calluna vulgaris, Ranunculus acris, Cerastium triviale, Potentilla Tormentilla, Trifolium repens, Stellaria media, Lotus corniculatus, Bellis perennis, Senecio vulgaris, Carduus palustris, Leontodon Taraxacum, Myosotis arvensis, Prunella vulgaris, Plantago lanceolata, Polygonum aviculare, Urtica dioica, Potamogeton natans, Lemna minor, Juncus effusus, Carex panicea, Poa annua, Festuca ovina, Anthoxanthum odoratum, Pteris aquilina, Polypodium vulgare, Lastrea Filix-mas. 2. English type—species chiefly o exclusively found in England, and decreasing in frequency northwards, constituting about 1-5th of the whole flora, as Rhamnus catharticus, Ulex nanus, Tamus communis, Bryonia dioica, Hottonia palustris, Chlora perfoliata, Sison Amomum, Moenchia erecta, Linaria Elatine, Ranunculus parviflorus, Lamium Galeobdolon, Hordeum pratense, Alopecurus agrestis, Ceterach officinarum, besides very local plants such as Cyperus longus and Cicendia filiformis. 3. Scottish type—species chiefly prevalent in Scotland or the north of England, forming about 1-20th of the flora, as Empetrum nigrum, Rubus saxatilis, Trollius europæus, Geranium sylvaticum, Trientalis europæa, Habenaria albida, Haloscias scoticum, Mertensia maritima; also Primula farinosa, Goodyera repens, Corallorhiza innata, and Saxifraga Hirculus, which are comparatively limited in their distribution and partial in their localities; besides some very local plants such as Arenaria norvegica, Primula scotica, and Ajuga pyramidalis. 4. Highland type-species either limited to the Scottish Highlands or extending to the mountains of the north of England and Wales; a more boreal flora than the last, the species being especially limited to the mountains or their immediate vicinity, and forming probably about 1-15th of the flora, as Azalea procumbens, Veronica alpina, Alopecurus alpinus, Phleum alpinum, Juncus trifidus, Sibbaldia procumbens, Erigeron alpinus, Gentiana nivalis; to these may be added the following, which, however, descend also lower, Salix herbacea, Silene acaulis, Saxifraga stellaris, Oxyria reniformis, Thalictrum alpinum, Luzula spicata, Juncus triglumis, Rubus Chamæmorus, Epilobium alsinifolium, Draba incana, Dryas octopetala, Alchemilla alpina; likewise some very local species, as Lychnis alpina and Oxytropis campestris. 5. Germanic typespecies chiefly seen in the east and south-east of England (bounded by the German ocean eastward)—forming about 1-15th or 1-20th of the flora, as Frankenia lævis, Anemone Pulsatilla, Reseda lutea, Silene noctiflora, Silene conica, Bupleurum tenuissimum, Pimpinella magna, Pulicaria vulgaris, Lactuca Scariola, Halimus pedunculatus, Aceras Anthropophora, Ophrys aranifera, Spartina stricta; also very local plants such as Veronica verna. 6. Atlantic typespecies found in the west and south-west of England and Wales, having a tendency to the western or Atlantic parts of the island-forming about 1-15th or 1-20th of the flora, as Sinapis monensis, Matthiola sinuata, Raphanus mariti-

mus, Sedum anglicum, Cotyledon Umbilicus, Eufragia vis- Botany. cosa, Pinguicula lusitanica, Euphorbia Peplis and E. Portlandica, Scirpus Savii; also more limited species, as Sibthorpia europæa, Erica vagans, E. ciliaris, Physospermum cornubiense, Polycarpum tetraphyllum, Adiantum Capillus-Veneris, Cynodon Dactylon. 7. Local or doubtful type—species which cannot be referred to any of the preceding types, as Potentilla rupestris, Lloydia serotina, confined to peculiar mountains in Wales, Draba aizoides and Cotoneaster vulgaris, found on the rocky coasts of Wales very locally, Draba muralis and Hutchinsia petræa; also Eriocaulon septangulare, found in the Isle of Skye, and formerly included under Watson's Hebridean type. If Ireland and the Channel Islands are also taken into account, Hibernian and Sarnian types would be added.

On ascending lofty mountains in Britain, there is a marked variation in the nature of the vegetation. On Ben-muich-Dhui, which attains an elevation of upwards of 4000 feet, Watson gives a full list of the species observed in succession. On leaving the plants of the low country we find Myrica Gale, extending on this mountain to 1400 feet, and in succession we came to the upper limits of the following species: - Erica cinerea, Pinus sylvestris, Carex pauciflora, Pedicularis sylvatica at 1838 feet, Tofieldia palustris, Erica Tetralix, at 2370 feet, Arctostaphylos Uva-Ursi, Thalictrum alpinum, Vaccinium Vitis-Idæa, Hieracium alpinum, Juniperus communis var. nana, at 2660 feet, Potentilla Tormentilla, Calluna vulgaris, 2690 feet, Azalea procumbens, Armeria maritima, Cochlearia gröenlandica, Arabis petræa, Rubus Chamæmorus, Epilobium alpinum, E. angustifolium, Vaccinium uliginosum, Sibbaldia procumbens, Saxifraga stellaris, Alchemilla alpina, Empetrum nigrum, Juncus trifidus, Gnaphalium supinum, and on the summit Silene acaulis, Carex rigida, Luzula arcuata and L. spicata, Salix

Considering British plants in climatic or ascending zones. they are divided by Watson into-

- I. Agrarian Region.—limited generally by the Pteris aquilina, and indicating the region of Corn cultivation. In the Highlands it may be said to extend as high at least as 1200 feet. It is subdivided into three zones:-
 - 1. Infer-agrarian Zone-embracing all the country southward from the Dee and Humber, except the mountainous parts of Wales, and the higher hills and moors in the provinces of the Severn and Peninsula (including Gloucester, Worcester, Warwick, Stafford, Hereford, Monmouth, Cornwall, Devon, and Somerset). Some of the peculiar species are Clematis Vitalba, Rubia peregrina, Cyperus longus, Erica
 - ciliaris, Sibthorpia europæa, and Scilla autumnalis.

 2. Mid-agrarian Zone—all the low grounds, clear from the mountains, situate between the entrance of the Clyde and Tay on the north, and those of the Humber and Dee on the south, also probably a narrow coast-line of the East Highlands, extending from Perth to Aberdeen, and possibly even to Inverness. Also a narrow belt extending round the hills of Wales. Rhamnus catharticus and Frangula, Tamus communis, Bryonia dioica, Acer campestre, Ulex nanus, Viburnum Lantana, Euonymus europæus, and Cornus sanguinea, occur in this zone, but are not re-
 - stricted to it. There is no Clematis. 3. Super-agrarian Zone-coast-line and low plains and

moors in the north and nort-west of Scotland, where alpine plants descend to the sea-shore; such as Thalictrum alpinum, Draba incana, Saxifraga oppositifolia, Arctostaphylos alpina, and Dryas octopetala. Also other parts where the elevation of the ground leads to the production of the same species, or of such plants as Arctostaphylos Uva-Ursi, Saxifraga stellaris, Alchemilla alpina, Tofieldia palustris, Juncus triglumis. Also tracts of slight elevation in the proximity of high mountains, upon which a corresponding flora prevails. At its lower limits appear Ilex, Corylus, Quercus, Fraxinus, Lonicera, Cratægus. and fruticose Rubi.

Botany.

- Botany.
- Arctic Region—characterized by the absence of Corn cultivation.
 - Infer-arctic Zone—this has its terminal line at the limit of Erica Tetralix.
 - Mid-arctic Zone—space above the limit of Erica Tetralix, and within or below that of Calluna vulgaris. In this zone most of the rare alpine plants are found, such as Saxifraga nivalis, Gentiana nivalis, Erigeron alpinus, Astragalus alpinus, Veronica alpina, Alopecurus alpinus, &c.
 - Super-arctic Zone—above the limit of Calluna, characterized by Saxifraga cernua and rivularis, and Luzula arcuata.

Professor Edward Forbes has followed Watson in his views of distribution, and has promulgated a theory in regard to the origin of the flora of Britain. He considers the vegetation of Great Britain and Ireland as composed of several floras, which are to be reckoned outposts separated by gcological changes from more extended areas. The following five floras, according to him, make up the vegetation of Britain and Ireland: 1. A west Pyrenean flora (Iberian or Asturian type), confined to the mountainous districts of the west and south-west of Ireland, characterized by botanical peculiarities, which depend on the presence of a few prolific species belonging to the families Saxifragaceæ, Ericaceæ, Lentibulariaceæ, and Cruciferæ. 2. A flora in the southwest of England and south-east of Ireland (Armorican type), which is intimately related to that of the Channel Isles and the neighbouring coast of France (Brittany and Normandy). This is Watson's Atlantic type. 3. The flora of the south east of England, where the rocks of the Cretaceous system are chiefly developed, and in which many species occur common to this district and the opposite coast of France. This corresponds nearly to Watson's Germanic type. 4. An alpine flora (Boreal or Scandinavian type), developed chiefly on the mountains of Scotland, and also partially on those of Cumberland and Wales. The species found on the latter are all, with the exception of Lloydia serotina, inhabitants also of the Scotch Highlands. The Scotch alpines all occur in Scandinavia, where they are associated with numerous additional species. This flora corresponds nearly to Watson's Highland type. This flora is represented in Shetland by Arenaria norvegica, and in Orkney by Primula scotica. It is largely developed on the Scottish Alps. 5. The general flora of the British slands, identical with that of central and western Europe, and which is called a Germanic flora. It corresponds to Watson's British, English, and Scottish types. It is a flora which overspreads many local floras throughout Europe, and gives a general character to the vegetation.

Forbes endeavours to prove that the specific identity, to any extent, of the plants of one area with those of another, depends on both areas forming, or having formed, part of the same specific centre, or on their having derived their vegetable population by transmission, through migration, over continuous or closely contiguous land, aided, in the case of alpine floras, by transportation on floating masses of ice. According to him, "the oldest of the floras now composing the vegetation of the British isles, is that of the mountains of the west of Ireland. Though an alpine flora, it is southernmost in character, and is quite distinct as a system from the floras of the Scottish and Welsh Alps. Its very southern character, its limitation, and its extreme isolation, are evidences of its antiquity, pointing to a period when a great mountain barrier extended across the Atlantic from Ireland to Spain. The distribution of the second flora, next in point of probable date, depended on the extension of a barrier, the traces of which still remain, from the west of France to the south-east of Britain, and thence to Ireland. The distribution of the third flora depended on the connexion of the coast of France and England towards the eastern part of the channel. Of the former

existence of this union no geologist doubts. The distribution of the fourth, or alpine flora of Scotland and Wales, was effected during the glacial period, when the mountain summits of Britain were low islands, or members of chains of islands, extending to the area of Norway through a glacial sea, and clothed with an arctic vegetation, which in the gradual upheaval of those islands and consequent change of climate, became limited to the summits of the new-formed and still existing mountains. The distribution of the fifth or Germanic flora, depended on the upheaval of the bed of the glacial sea, and the consequent connection of Ireland with England, and of England with Germany, by great plains, the fragments of which still exist, and upon which lived the great elk, and other quadrupeds now extinct. The breaking up or submergence of the first barrier led to the destruction of the second; that of the second to that of the third; but the well-marked epoch of migration of the Germanic flora indicates the subsequent formation of the straits of Dover, and of the Irish Sea, as now existing."

While there are evident and distinct features in the plants which constitute the floras of different parts of Britain, there are many difficulties to be overcome before we can adopt the speculative views of Forbes. The connection between the Tertiary and the present epoch is not made out as far as the species of plants are concerned, and we are disposed to look upon the existing flora of the globe as a distinct and independent one. Schouw differs from Forbes in his explanation of the flora of the British islands. He does not believe in the migration and geological changes to which Forbes alludes. He thinks that the west and south-west coast of Britain and Ireland had at first a mild climate, especially in winter, and that in consequence plants were produced there common to the analogous climates of Spain and the south of France; while the Scotch and English mountains were distinguished throughout by a polar climate, and produced nearly the same vegetation as the Lapland and Scandinavian mountains.

D'Archiac says, that in a botanical point of view, it would, perhaps, be desirable to determine whether the external circumstances under which the five floras of Great Britain now live, such as latitude, altitude, temperature, winds, humidity or dryness, exposure, nature of the soil, greater or less distance from the coast, &c., are altogether insufficient to explain their different characters. We know that plants have very different geographical limits. Thus there are some which we meet with over an extent of 25° in latitude, and much more in longitude, while others occupy only zones extremely restricted in both senses; it would, therefore, be useful to study the five British floras in this point of view. The radiation of plants from a centre is by no means satisfactorily proved; and it may be asked, for example, what is the original centre from which the species common to North America and southern Europe could have radiated? D'Archiac thinks that inconvenience arises from an attempt to give an account of facts hitherto inexplicable in one science, by drawing from another science suppositions made, as it appears, with the sole view of these explanations, and for which there is no sufficient authority. Proofs drawn from geology must rest on more certain data, he thinks, than those which have been adduced by Professor Forbes.

British marine vegetation presents two well-marked types according to Forbes, a southern and a northern. The genera Padina and Halyseris have their northern limit on the south coast of England, where they are rare. The genera Cystoseira, Sporochnus, Cutleria, and certain species of Sphacelaria, Mesogloia, Rhodymenia, Gigartina, and Dictyota, mark out a southern region, including the British Channel and part of the east coast, the Bristol Channel, and the south and west of Ireland; while the presence of Odonthalia dentata, Rhodomela cristata, R. lycopodioides, and Fucus Mackaii, characterize a northern flora, on the coasts of Scotland,

Botany. the north of England and of Ireland. The proportion of the different marine plants on the shores of Britain are as follows:-Melanospermez 1-5th, Rhodospermez 3-8ths,

and Chlorospermeæ 1-4th of the whole.

The British marine plants, according to Forbes, are distributed in depth or bathymetrically in a series of zones or regions which extend from high water mark down to the greatest explored depths. The first or littoral zone is that tract which lies between high and low water marks, and therefore is very variable in extent according to the amount of rise and fall of the tides. It has been divided into subregions characterized by the prevalence of certain marine species. 1. The sub-region of Fucus canaliculatus, 2. The sub-region of Lichina. 3. The sub-region of Fucus articulatus (Chylocladia articulata), F. nodosus, and Corallina officinalis. 4. The sub-region of Fucus serratus. The Lit-

toral zone is succeeded by narrow belts of such Seaweeds Botany. as Himanthalia lorea, Conferva rupestris, Laurencia pinnatifida, Chondrus crispus, and C. mammillosus. The second or Laminarian zone commences at low water-mark, and extends to a depth of from 7 to 15 fathoms. Here we meet with the great Tangle Seaweeds and deep-water Fuci. Species of Laminaria, Rhodymenia, and Delesseria, are found in an upper sub-region of this zone. In the lower sub-region they are rare, and are succeeded by the corallike Nullipore. The zones below them are entitled the Coralline zone, extending from 15 to 50 fathoms, and the region of the deep-sea corals from 50 to beyond 100 fathoms. These zones do not exhibit any conspicuous vegetable forms; they are characterized by the presence of certain animals. At the depth of 50 fathoms in the British seas, there seems to be a total absence of vegetable life

PART IV.

PALÆONTOLOGICAL BOTANY, OR THE STUDY OF FOSSIL PLANTS.

The changes which have taken place in the nature of living beings since their first appearance on the globe till the period when the surface of the earth having assumed its present form, has been covered by the creation which now occupies it, constitutes one of the most important departments in geology. It is, as Brongniart remarks, the history of life and its metamorphoses. The researches of geologists show clearly that the globe has undergone various alterations since that "beginning" when "God created the heavens and the earth." At various periods of the world's history, new mineral beds have covered the surface of the earth, and elevations of different portions of its crust have taken place, while at the same time the living beings inhabiting it have been buried in sedimentary deposits, to be replaced by a creation more or less different from the preceding. Some of these epochs have been marked apparently by great changes in the physical state of our planet, and they have been accompanied with equally great modifications in the nature of the living beings which inhabited The study of the fossil remains of animals is called Palæozoology, while the consideration of those of vegetables is denominated Palæophytology. Both are departments of the science of Palæontology, which has been the means of bringing geology to its present state of advancement. The study of these extinct forms has afforded valuable indications as to the physical state of the earth and as to its climate at different epochs.

The vegetation of the globe, during the different stages of its formation, has undergone very evident changes. the same time there seems to be no reason to doubt that the plants may all be referred to the great classes distinguished at the present day, namely, Thallogens, Acrogens, Gymnosperms, Endogens, and Exogens. The relative proportion of these classes, however, has been different, and the predominance of certain forms has given a character to the vegetation of different epochs. The farther we recede in geological history from the present day the greater is the difference between the fossil plants and those which now occupy the surface. At the time when the coal-beds were formed, the plants covering the earth belonged to genera and species not recognised at the present day. As we ascend higher, the similarity between the ancient and the modern flora increases, and in the latest stratified rocks we have in certain instances an apparent identity, at least as regards genera. At early epochs the flora appears to have

been uniform, to have presented less diversity of forms than at present, and to have been similar in the different quarters of the globe. The vegetation also seems to indicate that the nature of the climate was different from that which characterizes the countries in which these early fossil plants are now found.

Fossil plants are by no means so easily examined as They are seldom found in a complete recent species. state. Fragments of stems, leaves, and fruits, are the data by which the plant is to be determined. It is very rare to find any traces of reproductive organs. The parts of fossil plants are usually separated from each other, and it is very difficult to ascertain what are the portions which should be associated together so as to complete a specimen. The anatomical structure of some of the organs, especially of the stem, can sometimes be detected by thin microscopic slices being placed under the microscope; and in the case of Coniferous wood, the punctated woody tissue has proved

of great service as regards fossil Botany. Brongniart says that the mode in which plants are preserved in a fossil state may be referred to two principal classes:—1. The impression or cast of the plants, accom-

panied with the complete destruction of the vegetable tissue, and the preservation of few of its constituent parts. 2. Petrifaction and Carbonization, which preserve more or less completely the structure of the tissues of vegetable organs, by changing them completely or only modifying them. The first state is rather rare, but it is the usual condition of fossil vegetables in the variegated sandstone and tertiary limestones. The place of the vegetable is either empty or replaced by a substance of a ferruginous, calcareous, or earthy nature, having no organization. The second state or the impression with some preserved portion of vegetable tissue, is very frequent in the case of stems found in the carboniferous system. This is their ordinary mode of preservation. In such stems we must carefully distinguish the different zones of tissue, and their external and internal surfaces, which produce so many different appearances. The silicified stems of trees have been observed in various parts of the world, with their structure well preserved, so that their Endogenous and Exogenous character can be

easily determined. In order to study fossil plants well, there must be an acquaintance with systematic botany, a knowledge of the microscopical structure of all the organs of plants, such as

Botany, their roots, stems, barks, leaves, fronds, and fruit; of the markings which they exhibit on their different surfaces, and of the scars which some of them leave when they fall. It is only thus we can expect to determine accurately the living affinities of the fossil. Brongniart says, that before comparing a fossil vegetable with living plants, it is necessary to reconstruct as completely as possible the portion of the plant under examination, to determine the relations of these portions to the other organs of the same plant, and to complete the plant if practicable, by seeing whether, in the fossils of the same locality, there may not be some which belong to the same plant. The connection of the different parts of the same plant is one of the most important problems in Palæophytology, and the neglect of it has perhaps led to a needless multiplication of fossil species; portions of the same plant having been described as separate species or genera. In some instances the data have been sufficient to enable botanists to refer a fossil plant to a genus of the present day, so that we have fossil species of the genera Ulmus, Alnus, Pinus, &c. Sometimes the plant is shown to be allied to a living genus, but differing in some essential point, or wanting something to complete the identity, and it is then marked by the addition of the term ites, as Pinites, Thuites, Zamites, &c.

Before drawing conclusions as to the climate or physical condition of the globe at different geological epochs, the botanist must be well informed as to the vegetation of different countries, as to the soils and localities in which certain plants grow, whether on land or in the sea, or in lakes, in dry or marshy ground, in valleys or on mountains, or in estuaries, in hot, temperate, or cold regions. It is only by a careful consideration of all these particulars that any correct inferences can be drawn as to the condition of the globe.

The rocks of which the globe is composed are divided into two great classes, those which contain fossil remains, and which are called fossiliferous, and those having no such remains, and which are designated non-fossiliferous or azoic. The igneous unstratified rocks, included under the names of Granitic and Trappean, show no appearance of animal or vegetable remains. Trap rocks, however, have in some cases covered or inclosed vegetable structures, and these are found in an altered condition. Fossil remains have not been found in certain rocks having a stratified appearance, and which, from the changes they have undergone, were denominated by Hutton Metamorphic. These include Gneiss and Mica-slate, which are looked upon as stratified rocks, which have probably been formed at a high temperature, and have been subsequently altered by the effects of The absence of organic remains in rocks, however, is not always sufficient to enable us to state that these rocks were formed before animals or vegetables existed. Forbes has shown that, even at the present day, there are depths in the ocean which are destitute of organic life. Hence rocks deposited at such depths might contain no organic remains.

The stratified rocks which contain fossils have been divided into three great groups, the Palæozoic, the Secondary, and the Tertiary. The formations included under these are exhibited in the following table, as condensed from Ansted's geology:-

- 1. PALÆOZOIC ROCKS, containing the earliest fossil remains. They include the transition, Primary fossiliferous and Grauwacke rocks.
 - 1. Lower Palæozoic.-These comprehend the Silurian and Cambrian rocks.
 - 2. Middle Palæozoic.-The Devonian system, or Old Red Sandstone, so well developed in Scotland.
 - 3. Upper Palæozoic.—The Carboniferous system, or the Coal Measures, with millstone grit, carboniferous limestone and shales; and the Permian system, or the magnesian limestone.
- II. SECONDARY OF MEZOZOIC ROCKS, constituting a second great epoch in the history of fossils. VOL. V.

1. Lower Secondary .- The Upper New Red Sandstone of Botany. Britain, or the Triassic system of Germany. Here we meet with Red Sandstone and conglomerates, saliferous red and variegated marks.

2. Middle Secondary .- The Liassic system, with its limestones and marls; the Oolitic divided into Lower Oolite (Calcareous sand, Stonesfield slate, Bradford clay, &c.), Middle Oolite (Oxford clay, Coral clay, Calc grit, &c.), and Upper Oolite (Kimmeridge clay, Portland stone); the Wealden, as illustrated in Purbeck beds and Hastings sand.

3. Upper Secondary .- The Cretaceous system, with its lower and upper greensand and chalks, and the Gault. III. TERTIARY OF CAINOZOIC ROCKS, constituting the third grand fossiliferous epoch. These are well developed in Asia, America, and in the south of Europe, and only partially in Britain.

1. Lower Tertiary or Eccene.—This is seen in the London clay, the Paris basin, the Basin of Brussels, &c.

2. Middle Tertiary or Miocene. This is shown in the Coralline and Red Crag of Britain, the Basin of the

Rhine, of the Loire, and Garonne, &c.
3. Upper Tertiary or Pliocene.—This is illustrated by the Norwich crag, the Till of the Clyde, the Brown coal of Germany, &c.

These are succeeded by Superficial or Pleistocene Deposits, which consist of diluvium or diluvial drift, formed of gravel, with boulders, which indicate the violent action of water; and alluvium or deposits of fine mud, resembling those caused by ordinary fluviatile action. The tertiary formations and those of the present day appear to pass into each other.

The plants found in different strata are either terrestrial or aquatic, and the latter exhibit species allied to the salt and fresh-water vegetables of the present day. Their state of preservation depends much on their structure. Cellular plants have probably in a great measure been destroyed or changed in their aspect, and hence their rarity; while those having a woody and vascular structure have been preserved. The following is the number of fossil genera and species, as compiled from Unger's work on Palæophytology:-

Botany.

On taking a general survey of the known fossil plants, Brongniart thinks that he can trace three periods of vegetation, characterized by the predominance of certain marked forms of plants. In the most ancient period there is a predominance of Acrogenous Cryptogamic plants; this is succeeded by a period in which there is a preponderance of Gymnospermous Dicotyledons; while a third period is marked by the predominance of Angiospermous Dicotyledons. There is thus-1. The reign of Acrogens, which includes the plants of the Carboniferous and Permian periods. During these periods, there seems to be a predominance of Ferns, a great development of Lycopodiaceæ, arborescent forms of Lepidodendron and Sigillaria, Gymnosperms allied to Araucaria, and anomalous Gymnosperms, as Nöggerathia. 2. The reign of Gymnosperms, comprehending the lower and middle secondary periods. Here we meet with numerous Coniferæ and Cycadaceæ, while Ferns are less abundant. 3. The reign of Angiosperms, embracing the Cretaceous and the Tertiary periods. This is characterized by the appearance of Angiospermous Dicotyledons, a class of plants which constitute more than threefourths of the present vegetable productions of the globe, and which appear to have acquired a predominance from the commencement of the Tertiary formations. These plants appear even at the beginning of the Chalk formation.

I. Reign of Acrogens.—In the lower Palæozoic strata the plants which have been detected are few. In the Silurian, Cambrian, and Old Red Sandstone systems, we meet with the remains of ancient marine plants, as well as a few terrestrial species. In the Old Red Sandstone of Scotland, Miller has detected Fucoids, Ferns, a Lepidodendron, and Lignite with a distinct Coniferous structure resembling that of Araucaria, besides a remarkable pinnate frond. In the Old Red Sandstone rocks at Oporto, Bunbury detected Pecopteris Cyathea, P. muricata, and Neuropteris tenuifolia —ferns allied to those of the Coal Measures.

The Carboniferous period is one of the most important as regards fossil plants. The vegetable forms are numerous and uniform throughout the whole system, whether exhibited in the Old or the New World. The important substance called Coal owes its origin to the plants of this epoch. It has been formed under great pressure, and hence the appearance of the plants has been much altered. On examining thin sections of coal under the microscope, we can detect vegetable tissues both of a cellular and vascular nature. In Wigan cannel coal, vegetable structure is seen throughout the whole mass. Such is likewise the case with other cannel, parrot, and gas coals. In common household coal, also, evident traces of organic tissue have been observed. In some kinds of coal punctated woody fibre has been detected, in others dotted and scalariform tissue, as well as cells of different kinds. Sporangia are also occasionally found in the substance of coal, as shown by Mr Daw in that from Fordel. The structure of coal in different beds, and in different parts of the same bed, seems to vary according to the nature of the plants by which it has been formed. Hence the different varieties of coal which are worked. The occurrence of scalariform and dotted vessels in coal indicates the presence of Ferns, and their allied forms, such as Sigillaria, Stigmaria, and Lepidodendron; while true punctated wood (which is rarely seen except in brown coal) implies the presence of Coniferæ. The anatomical structure of the stems of these plants will undoubtedly have some effect on the microscopic characters of the coal produced from them. The proportion of carbon varies in different kinds of coal. Along with it there is always more or less of earthy matter, which constitutes the ashes. When the earthy substances are in such quantity that the coaly deposit will not burn as fuel, then we have what is called a shale. The coal contains plants similar to those of the

shales and sandstones above and below it. In a coal-seam there is the Under-clay, containing roots only; then the Coal composed of plants, whose roots are in the clay, with others which have grown along with them, or have been drifted; while above the coal is the Shale bearing evidences of vigorous vegetation, and which appears like a great deposit from water charged with mineral matter, into which broken pieces of plants have fallen. There is frequently no clear division between coal and shale.

Unger enumerates 683 plants of the coal measures, while Brongniart notices 500. Of the last number there are 6 Thallogens, 346 Acrogens, 135 Gymnosperms, and 13 doubtful plants. This appears to be a very scanty vegetation, as far as regards the number of species. It is only equal to about 1-20th of the number of species now growing on the surface of the soil of Europe. Although, however, the number of species was small, yet it is probable that the individuals of a species were numerous. The proportion of Ferns was very large. There are between 200 and 300 enumerated.

Ferns are the only carboniferous fossil group which present an obvious and recognisable relationship to an order of the present day. While cellular plants and those with lax tissues often lose their characters by fossilization, Ferns are more durable, and retain their structure. It is rare, however, to find the stalk of the frond completely preserved down to its base. It is also rare to find fructification present. In this respect, fossil Ferns resemble Tree-ferns of the present day, the fronds of which rarely exhibit fructification. Only one surface of the Fern-frond is exposed to view, and that generally the least important in a botanical point of view. Fructification is sometimes evidently seen, as figured by Corda in Senttenbergia. The absence of fructification presents a great obstacle to the determination of fossil Ferns. The Acrogenous flora of the coal epoch seems to favour the idea of a humid as well mild and equable climate at the period of the coal formation—the vegetation being that of islands in the midst of a vast ocean.

Among the Ferns found in the clays, ironstones, and sandstones of the Carboniferous period, we may give the characters of some by way of illustration. Pecopteris seems

to be the fossil representative, if not congener, of Pteris. Pecopteris heterophylla (Fig. 583) has marked resemblance to Pteris esculenta New Zealand. The frond of Pecopteris pinnatifid or bitri-pinnatifidthe leaflets adhering to the rachis by the whole ength of their base, sometimes confluent; the midrib of the leaflets runs to the point, and the veins come off from it nearly

perpendicularly, and the fructification when present is at the ends of the veins. Neuropteris (Figs. 584 to 586), has a pinnate or bipinnate frond, with pinnæ somewhat cordate

Botany. at the base—the midrib of the pinnæ vanishing towards the apex, and the veins coming off obliquely, and in an arched manner. Neuropteris gigantea (Fig. 585) has a thick bare rachis, according to Miller, and seems to resemble much Osmunda regalis. Sphenopteris (Fig. 587) has a twice or thrice-pinnatifid frond, the leaflets being narrowed at the base, often wedge-shaped, and the veins generally arranged as if they radiated from the base. Sphenopteris elegans resembled Pteris aquilina in having a stout leafless rachis, which divided at a height of seven or eight inches from its club-like base into two equal parts, each of which continued to undergo two or three successive bifurcations. A little below the first forking two divided pinnæ were sent off. A very complete specimen, with the stipe, was collected in the coal-field near Edinburgh, by Hugh Miller, who has described it as above. Cyclopteris (Fig. 588) has simple orbicular leaves, undivided or lobed at the margin, the veins radiating from the base, with no midrib. Caulopteris is the name given to the stems of Tree-ferns found in the coal fields. They are marked externally by oblong scars similar to those of Tree-ferns of the present day. These stems probably belong to some of the fronds to which other names are given, but as they have not been found attached, it is impossible to determine the point.

Sigillaria is perhaps the most important plant in the coal formation. It is found in all coal shales over the world. There are upwards of 60 species. It occurs in the form of lofty stems, 40-50 feet high, and 5 feet broad (Figs. 589 and 590), standing erect at right angles to the planes of al-

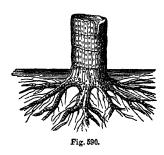

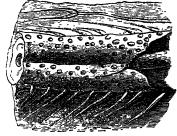

Fig. 589. Stems of Sigillaria pachyderma in an erect position, covered by successive deposits of sandstone and shale; one is bifurcated. ... 590. Sigillaria stem with markings, and Stigmaria roots.

ternating strata of shale and sandstone. The stem of Sigillaria is fluted in a longitudinal manner, and has a succession of single and double scars, which indicate the points of insertion of the leaves. When the outer part of the stem separates like bark, it is found that the markings presented by the inner surface differ from those seen externally. This has sometimes given rise to the erroneous supposition that they belong to different genera. In Sigillaria elegans there is a woody system which is broken up into cuneiform plates, separated by medullary rays, and there are two vascular systems, one forming a series of bundles in the medullary axis of the stem, and another external to the woody system. The vessels are dotted, scalariform, and more or less referrible to the spiral type. The external bundles which go directly to the leaves are placed opposite to the woody wedges (not, as in Stigmaria, opposite to the medullary rays), and such is also the case with the inner vascular system.

It has been recently ascertained by Mr Binney of Manchester, that the plant called Stigmaria (Fig. 591) is not a separate genus, but the root, or rather the rhizome of Sigillaria. It is one of the most common productions of the coal measures, and consists of long rounded or compressed fragments, marked externally by shallow circular, in some species they occupy the faces of diamond-shaped

oblong, or lanceolate cavities in the centre of slight tu-

bercles, arranged irregularly, but sometimes in a quincuncial manner. The cavities occasionally present a radiating appearance. The axis of the fragments is often hollow, and different in texture from the parts around. This axis consists of a vassystem, divided into
wedge-shaped masses
by medullary rays of
of a Sigillaria. The markings are the points
whence rootlets proceed. cular cylinder or woody

originate probably from the outer cellular axis, and not from the central woody cylinder. From the scars and tubercles arise long ribbon-shaped processes, which appear to have been hollow roots compressed. Stigmaria ficoides (Fig. 591), is often found creeping in the under-clay of a coal seam, sending out numerous roots from its tubercles, and pushing up its aerial stem, in the form of a fluted Sigillaria. While the rhizomes, stem, and roots have thus been determined, we have no means of ascertaining the foliage. It probable that Sigillaria was an acrogenous plant allied to Lycopodiaceæ, and probably intermediate between that order and Cycadaceæ. In coal from Fordel Mr Daw has detected numerous seed-like organisms, which may be the fructification either of a Sigillaria or of some plant allied to Lycopodium. The same bodies have been seen by Dr Fleming in many specimens of Cherry, Splint, and Cannel Coals from various quarters.

Lepidodendron (Fig. 592), is another genus of the coal measures which differs from those of the present day. It seems to occupy an intermediate place between Lycopodiaceæ and Coniferæ. The stem is from 20 to 45 feet high, marked outside by peculiar scaly-like scars (Fig. 592, a), hence the name of the plant. The linear or lanceolate leaves are arranged in the same way as those of Lycopodiums or of Coniferæ, and the branches fork like the former.

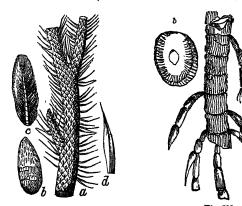

Fig. 592.

Fig. 593.

Fig. 592. Lepidodendron obovatum (elegans); a, bifurcating stem; b, Lepidostrobus; a, the same out vertically; d, Lepidophyllum.

593. Calamites Lindleyi (C. Mongeotii L. and H.), a jointed reed-like stem, with furrows on the surface. Stem a, with branches according to some, roots according to Binney; b, partition of one of the joints.

There is a double vascular system in the trunk, one in the centre, and another placed externally to the woody mass. The latter vascular system forms a continuous zone outside the wood; its inner edge is well defined, and its outer, whence bundles are given off to the leaves, is sinuous. Although the scars on Lepidodendron are usually flattened, yet

Botany.

projections, elevated one-sixth of an inch or more above the surface of the stem, and separated from each other by deep furrows:—the surface bearing the leaf being perforated by a tubular cavity, through which the bundle of vessels that diverged from the vascular axis of the stem to the leaf passed out. The fruit of Lepidodendron is seen in Lepidostrobus (Fig. 592, b and c), which appears to consist of scales covering sporangia, in the interior of which are spores, consisting of three or four angular sporules, which have been seen in a separate state. It is probable that many other fossil forms are connected with or allied to Lepidodendrons. Thus Lepidophyllum (Fig. 592, d) is probably the leaf of some species of the genus, while Strobilites is a form of the fruit.

Calamites (Fig. 593) is a reed-like fossil, having a subcylindrical, furrowed, and jointed stem, the furrows of the joints alternating and often converging. The stem is often crushed and flattened, and may probably have been originally hollow. At the joints there are toothed sheaths or tubercles, which are disposed symmetrically between the furrows. The fructification is unknown. There appears to have been a bark which could be separated from the woody tissue below. The plants have been seen erect by Mr Binney, and he has determined that what were called leaves or branches by some, are in reality roots. There are 51 species recorded. They have been compared to Equisetaceæ.

True Exogenous trees exist in the carboniferous system both of England and Scotland. These Exogenous trees are Gymnosperms, having woody tissue like that of Coniferæ. We see under the microscope punctated woody tissue, the rows of disks being usually two, three, or more, and alternating. They seem to be allied in these respects to Araucaria and Eutassa of the present flora. Stems of Dadoxylon or Pinites Withami, D. medullare, and Peuce Withami have been found in the sandstone of Craigleith quarry, near Edinburgh. Sternbergia is considered by Williamson as a Dadoxylon, with a discoid pith like that seen now-a-days in the Walnut and Jessamine.

The plants of the coal measures seem to be evidently terrestrial plants, and fresh-water aquatics. Brongniart agrees with Lyell in thinking that the lavers of coal have in general accumulated in the situation where the plants forming them grew. The remains of these plants covered the soil in the same way as layers of peat, or the vegetable mould of great forests. In a few instances, however, the plants appear to have been transported from a distance, and drifted into basins. Phillips is disposed to think that this was the general mode of formation of coal basins. He is led to this conclusion by observing the fragmentary state of the stems and branches, the general absence of roots, and the scattered condition of all the separable organs. Those who support the drift theory, look on the coal plants as having been swept from the land on which they grew by watery currents at different times, and deposited in basins and large sea-estuaries, and sometimes in lakes. The snags in the Mississippi, the St Lawrence, and other large rivers, are given as instances of a similar drifting process.

The nature of the vegetation during the Permian Period, which is associated with the Carboniferous, under the reign of Acrogens, has not been positively determined. genera of Ferns here met with are also found in the Carboniferous epoch; the Gymnosperms are chiefly species of Walchia and Nöggerathia. Lepidodendron elongatum, Calamites gigas, and Annularia floribunda, are also species of this period.

II. Reign of Gymnosperms.—In this reign the Acrogenous species are less numerous, the Gymnosperms almost equal them in number, and ordinarily surpass them in frequency. There are two periods of this reign, one in which Coniferæ predominate, while Cycadaceæ scarcely appear, and another in which the latter family preponderates as regards the number of species, and the frequency and variety

of generic forms. Cycadaceæ occupied a more important Botany, place in the ancient than in the present vegetable world. They extend more or less from the coal formation, up to the Tertiary. They are rare in the Grès-bigarré, or lower strata of the Triassic system (Upper New Red Sandstone) and in the Chalk. They attain their maximum in the Lias and Oolite, in each of which upwards of 40 species have been enumerated, and they disappear in the Tertiary formations.

In Brongniart's Vosgesian period, the Grès-bigarré, or the Red Sandstones and Conglomerates of the Triassic system, there is a change in the flora. Sigillarias and Lepidodendrons disappear, and in their place we meet with Gymnosperms, belonging to the genera Voltzia, Haidingera, Zamites, Ctenis, Æthophyllum, and Schizoneura. Species of Neuropteris, Pecopteris, and other acrogenous coal genera are still found, along with species of Anomopteris and Crematopteris-peculiar Fern-forms, which are not found in later formations. In the saliferous red and variegated marls of the Triassic system, the Acrogens are changed as regards species, and frequently in the genera. Thus we have the genera Camptopteris, Sagenopteris, and Equisetum. Among Gymnosperms, the genera Pterophyllum and Taxodites occur.

In the Lias the essential characters of the flora are the predominance of Cycadaceæ, in the form of species of Cycadites, Otozamites, Zamites, Ctenis, Pterophyllum, and Nilsonia, and the existence among the Ferns of many genera with reticulated venation, such as Camptopteris and Thaumatopteris. Coniferous genera, as Brachyphyllum, Taxodites, Palissya, and Peuce, are found.

In the Oolitic epoch, the flora consists of numerous Cycadaceæ and Coniferæ, some of them having peculiar forms. Its distinctive characters are, the rarity of Ferns with reticulated venation, which are so numerous in the Lias, the frequency of the Cycadaceous genera Otozamites and Zamites, which are most analogous to those now existing; and the greater frequency of the Coniferous genera, Brachyphyllum and Thuites.

There is an absence of true coal fields in the secondary formations generally; but in some of the Oolitic series, as in the lower Oolite at Brora, in Sutherlandshire, and the Kimmeridge clay of the upper Oolite, near Weymouth, there are considerable deposits of carbonaceous matter. The upper Oolite at Portland contains an interesting bed about a foot in thickness, of a dark brown substance, containing much earthy lignite. This is the dirt-bed, made up of black loam, which, at some far distant period, nourished the roots of trees, fragments of whose stems are now found fossilized around it. These consist of an assemblage of silicified stumps or stools of large trees, standing from 1-3 feet from

Fig. 504.

Fig. 594. Cycadoidea megalophylla (Mautellia nidiformis of Brongniart), a sub-globose depressed trunk, with a concave apex, and with the remains of the petioles disposed in a spiral mainer, the markings being transversely elliptical. It is found in the Oolite of the Island of Portland, in a silicified state.

595. Zamiostrobus ovatus (Zamia ovata of Lindley and Hutton), an ovate cone with a truncated base and obtuse apex. The genus seems to be intermediate between Encephalartos and Zamia. It is found in the green-sand at Faversham (Lindley and Hutton).

the mould. Most of them are erect, some slightly inclined,

Botany.

Botany, and the roots remain attached to the earth in which they grew. They appear to resemble Cycadaceæ. One of these is Cycadoidea megalophylla, shown in Figure

> The flora of the Wealden epoch is characterized in the north of England by the abundance of the Fern called Lonchopteris Mantellii, and in Germany by the predominance of the Conifer denominated Abietites Linkii, as well as by numerous Cycadaceæ, such as species of Cycadites, Zamites, Pterophyllum, Zamiostrobus (Fig. 595), Cycadoidea, Clathraria. Mantell states that he has found 40 or 50 fossil cones in the Wealden of England. The remains are those of land vegetables. The Wealden fresh water formation terminates the reign of Gymosperms.

III. Reign of Angiosperms. - This reign is characterized by the appearance of Angiospermous Dicotyledons, plants which constitute more than three-fourths of the present vegetable productions of the globe, and which appear to have acquired the predominance from the commencement of the Tertiary epoch. These plants, however, appear even at the beginning of the Cretaceous period. In this reign, therefore, Brongniart includes the upper secondary period, or the Cretaceous system, and all the Tertiary period. The Cretaceous may be considered as a sort of transition period between the reign of Gymnosperms and Angiosperms. The Chalk flora is characterized by the Gymnospermous almost equalling the Angiospermous Dicotyledons, and by the existence of a considerable number of Cycadaceæ, which do not appear in the Tertiary period. The genus Credneria is one of the characteristic forms.

The Tertiary period is characterized by the abundance of Angiospermous Dicotyledons and of Monocotyledons, more especially of Palms. By this it is distinguished from the more ancient periods. Angiosperms at this period greatly exceed Gymnosperms. Cycadaceæ are completely wanting in the European Tertiary strata, and the Coniferæ belong to genera of the temperate regions. Although the vegetation throughout the whole of the Tertiary period presents pretty uniform characters, still there are notable differences in the generic and specific forms, and in the predominance

of certain orders at different epochs.

The Eocene epoch in general is characterized by the predominance of Algæ and marine Naiadaceæ, such as Caulinites and Zosterites; by numerous Coniferæ, the greater part resembling existing genera among the Cupressineæ, and appearing in the form of Juniperites, Thuites, Cupressites, Callitrites, Frenelites, and Solenostrobus; by the existence of a number of Extra-European forms, especially of fruits, such as Nipadites, Leguminosites, Cucumites, and Hightea; and by the presence of some large species of Palm belonging to the genera Flabellaria and Palmacites. Amber is considered to be the produce of many Coniferæ of this epoch, such as Peuce succinifera.

The most striking characters of the Miocene epoch consist in the mixture of exotic forms of warm regions with those of temperate climates. Thus we meet with Palms, a kind of Bamboo, and other plants of warm climates, mingled

with Amentiferous and other forms, belonging to temperate and cold climates.

The flora of the Pliocene epoch has a great analogy to that of the temperate regions of Europe, North America, and Japan. We meet with Coniferæ, Amentiferæ, Rosaceæ, Leguminosæ, Rhamnaceæ, Aceraceæ, Aquifoliaceæ, Ericaceæ, and many other orders. There is a small number of Dicotyledons with gamopetalous corollas. In this flora there is the predominance of Dicotyledons in number and variety; there are few Monocotyledons and no Palms. No species appear to be identical, at least with the plants which now grow in Europe.

Brown coal occurs in the upper Tertiary beds, and in it vegetable structure is easily seen under the microscope. Goeppert, on examining the brown coal deposits of northern Germany and the Rhine, finds that Coniferæ predominate in a remarkable degree; among 300 specimens of bituminous wood collected in the Silesian brown coal deposits alone, only a very few other kinds of Dicotyledonous wood occur. The coniferous plants of these brown coal deposits belong to Taxineæ and Cupressineæ chiefly; among the plants are

Pinites Protolarix and Taxites Ayckii.

We have thus seen that the vegetation of the globe has undergone various changes at different periods of its history, and that the farther back we go, the more are the plants different from those of the present day. There can be no doubt that there have been successive deposits of stratified rocks, and successive creations of living beings. We see that animals and plants have gone through their different phases of existence, and that their remains in all stages of growth and decay have been imbedded in rocks superimposed upon each other in regular succession. It is impossible to conceive that these were results of changes produced within the limits of a few days. Considering the depth of stratification, and the condition and nature of the living beings found in the strata at various depths, we must conclude (unless our senses are mocked by the phenomena presented to our view) that vast periods have elapsed since the Creator in the beginning created the heavens and the earth.

When we find animals and plants of forms unknown at the present day, in all conditions as regards development, we read a lesson in regard to the history of the earth's former state as conclusive as that which is derived from the Nineveh relics (independent of Revelation) in regard to the history of the human race. There is no want of harmony between Scripture and geology. The Word and the Works of God must be in unison, and the more we truly study both, the more they will be found to be in accordance. Any apparent want of correspondence proceeds either from imperfect interpretation of Scripture or from incomplete knowledge of science. The changes in the globe have all preceded man's appearance on the scene. He is the characteristic of the present epoch, and he knows by Revelation that the world is to undergo a further transformation, when the elements shall melt with fervent heat, and when all the present state of things shall be dissolved ere the ushering in of a new earth, wherein righteousness is to dwell.

EXPLANATION OF THE PLATES.

Plate CX. Helleborus fœtidus, Stinking Hellebore, belonging to the Nat. Ord. Ranunculaceæ, Sub-ord. Helleboreæ. The leaves

are pedate, the inflorescence cymose, and the fruit follicular.

Plate CXI. Drimys Winteri, Winter's bark plant, belonging to the Nat. Ord. Magnoliaceæ, and Sub-ord. Wintereæ. The plant was discovered by Captain Winter. Its bark is aromatic and stimulant, and its leaves are dotted.

Plate CXII. Papaver Rhœas, common Red Poppy, belonging to the Nat. Ord. Papaveraceæ. The leaves are pinnatifid, the peduncles have spreading hairs, the calyx consists of 2 caducous sepals, inclosing 4 crumpled petals, the stamens are indefinite and hypogynous, and the ovary is surmounted by a radiating

1. Stamens inserted on the thalamus, below the ovary with its sessile stigma.

2. Capsule of the Poppy opening by pores below the sessile stigma.

Plate CXIII. Janipha Manihot and Eschscholtzia californica.

Fig. 1. Janipha Manihot, Cassava plant, belonging to the Nat. Ord. Euphorbiaceæ. The leaves are digitately-partite, and the flowers are in racemose cymes.

Fig. 2. Racemose cyme, with a pentacoccous capsule, which

separates in an elastic manner into 5 single-seeded carpels. The cyme bears male as well as female flowers.

Fig. 3. Pistil with stigma.

Fig. 4. Stamens and fleshy disk.

Fig. 5. Seed with strophiole. Fig. 6. Eschscholtzia californica (nat. size), belonging to the Nat. Ord. Papaveracess. It has multipartite leaves, a peculiar caducous calyx like a candle-extinguisher, and a tetrapetalous corolla, with numerous hypogynous stamens.

Fig. 7. Hollowed end of the peduncle, with the pistil. The

calyx separates in one piece from the peduncle.

Fig. 8. Section of ovary, with numerous seeds attached to 2 parietal placentas.

Fig. 9. Ceratium or Siliquæform capsule (nat. size), opening by 2 valves, and bearing seeds on each margin of the valves.

Fig. 10. Section of the seed, with the Dicotyledonous embryo. Fig. 11. Embryo separated from the seed, showing the 2 cotyledons and the radicle.

Plate CXIV. Malva sylvestris, common Mallow, belonging to the Nat. Ord. Malvaceæ. The leaves have 5 lobes, the inflorescence consists of cymose fascicles, the æstivation is contorted, petals 5 obcordate, and stamens monadelphous.

Fig. 1. Calyx with a three-leaved epicalyx or involucre.

Fig. 2. Obcordate petal, with monadelphous stamens.

Fig. 3. Tube of stamens formed by union of the filaments.

Fig. 4. Pistil with numerous carpels and styles.

Fig. 5. Stamen with reniform anther opening round the margin.

Fig. 6. Section of ovary composed of numerous carpels.
Plate CXV. Linum catharticum, and Linum usitatissimum, belong-

ing to the Nat. Ord. Linaces.

Fig. 1. Linum catharticum, Purging Flax, having opposite oblong leaves, and a corymbose cyme.

Fig. 2. Linum usitatissimum, Common Flax, having alternate lanceolate leaves and a corymbose cyme.

Plate CXVI. Anacardium occidentale, Cashew-nut plant, belonging to the Nat. Ord. Anacardiaceæ.

Fig. 1. Branch (somewhat reduced), bearing flowers and fruit. The flowers are in cymes, and the peduncles are enlarged in a pear-like form, bearing the nut (the true fruit) at their apex.

Fig. 2. Flower not expanded, showing calyx and petals, with single fertile stamen and pistil.

Fig. 3. Flower expanded.

Fig. 4. Stamen and pistil, with the calyx. One fertile stamen longer than the others.

Fig. 5. Stamen separated.

Fig. 6. Nut constituting the fruit. Fig. 7. Nut opened longitudinally. Fig. 8. Seed separated from the nut.

Fig. 9. Cotyledons opened to show the radicle a, and the

Plate CXVII. Sarothamnus scoparius (Spartium or Cytisus of many anthers), Common Broom, belonging to the Nat. Ord. Leguminosæ or Fabacæ, Sub-ord. Papilionaceæ. The angled branches bear ternate leaves, papilionaceous flowers, and legumes.

Fig. 1. Two-lipped calyx.

Fig. 2. Broadly ovate Vexillum or standard.

Fig. 3. One of the Alæ, or wings, of the corolla.

Fig. 4. Carina or Keel, which consists of 2 petals, and incloses

the essential organs of reproduction.

Fig. 5. Monadelphous stamens, i.e. united into a tube by their filaments

Fig. 6. Hairy ovary with the long style, thickened upwards, and spirally curved.

Fig. 7. Legume or Pod, many-seeded and hairy at the margin.

Plate CXVIII. Carica Papaya and Andromeda hypnoides.

Fig. 1. Carica Papaya, the Papaw tree (much reduced), belonging to the Nat. Ord. Papayacee. The leaves are palmatelycleft, and the flowers are unisexual.

Fig. 2. Portion of a racemose cyme of infundibuliform male flowers, with united petals.

Fig. 3. Gamopetalous male flower cut open, showing the ten epicorolline stamens alternately shorter.

Fig. 4. Stamen consisting of filament and anther lobes.

Fig. 5. Female flowers with a deeply-5-parted corolla and 5 stigmas above the ovary.

Fig. 6. Andromeda hypnoides (nat. size), belonging to the Nat. Ord. Ericacese, with a creeping moss-like stem and pendulous, solitary, somewhat bell-shaped flowers.

Fig. 7. Flower of Andromeda, with 5-parted calyx, gamopetalous, campanulate corolla.

Fig. 8. Back view of stamen with its 2-horned anther.

Fig. 9. Front view of stamen with bicornute and biporose anther.

Fig. 10. Pistil with its ovate acuminate style and 5-grooved Botany.

Fig. 11. Capsule, 5-celled, with a central 5-lobed placenta

bearing numerous ovules.

Plate CXIX. Æthusa Cynapium, Fool's Parsley, belonging to the
Nat. Ord. Umbelliferæ. The leaves are bipinnate or tripinnate, with a sheathing pericladium, flowers in compound umbels, with a reflexed unilateral. 3-leaved involucel connected with the

Plate CXX. Conium maculatum, Common Hemlock, belonging to the Nat. Ord. Umbelliferæ. The stem is spotted and hollow, leaves compound (tripinnate), with a pericladium, flowers in compound umbels, with an involucre and an involucel, fruit a cremocarp with waved ridges.

Plate CXXI. Œnanthe crocata, Hemlock Water-Dropwort, belonging to the Nat. Ord. Umbelliferæ. Leaves compound and sheathing, roots composed of fusiform sessile knobs, stem hollow, and flowers in compound umbels, with general and partial involucres.

Fig. 1. Flower composed of 5 petals, with inflexed apicula, 5 stamens, and 2 styles with an epigynous disk.

Fig. 2. Lateral view of the cremocarp composed of 2 mericarps or achenes, with blunt convex ribs, surmounted by the lanceolate teeth of the calyx, and two styles with a disk at their base.

Fig. 3. Back view of the cremocarp, with ribs, teeth of calvx, and styles.

Plate CXXII. Valeriana officinalis, Great Wild Valerian, belonging to the Nat. Ord. Valerianaceæ, showing the roots, which are officinal, the hollow stem, the alternately-pinnate leaves, and flowers in corymbose cymes.

Fig. 1. Separate flower, consisting of an adherent calyx, with an obsolete limb, an irregular gamopetalous corolla, exserted stamens, and 1 style.

Fig. 2. Pistil separated, with ovary, style, and stigma.

Fig. 3. Monospermal fruit, with the persistent pappose limb of the calyx.

Plate CXXIII. Lactuca virosa, Strong-scented Wild Lettuce, belonging to the Nat. Ord. Compositæ, Sub-ord. Cichoraceæ. leaves are sessile, amplexicaul at the base, and dentate. The flowers in capitula, and the calyx pappose.

Plate CXXIV. Leontodon Taraxacum, Common Dandelion, belonging to the Nat. Ord. Compositæ, Sub.-ord. Cichoraceæ. The leaves are radical and runcinate, the flowers ligulate, and arranged in capitula. The outer phyllaries (involucral leaves) are reflexed, and all of them become deflexed when the fruit is ripe; the receptacle becomes dry and convex.

Fig. 1. Capitulum with reflexed phyllaries and ligulate flowers. Fig. 2. A single flower, with inferior achene (cypsela), stipitate pappus, a ligulate corolla, 5 stamens united by their anthers, and 1 style with 2 stigmas.

Fig. 3. Receptacle of the flowers, become dry and convex, with deflexed phyllaries, so as to allow the pappose fruit to be scat-

Fig. 4. Linear-obovate Achene, or Cypsela, consisting of an indehiscent single-seeded seed-vessel, which is muricated towards the apex, and longitudinally striated.

Plate CXXV. Cuscuta verrucosa, Warty Dodder, belonging to the Nat. Ord. Cuscutaceæ, which is often considered as a sub-order of Convolvulaceæ.

Fig. 1. Leafless flowering stem of Dodder (nat. size) turning from right to left (contrary to the motion of the sun), and bearing racemose cymes

Fig. 2. Campanulate corolla, cut open, showing 5 epicorolline stamens, with alternating scales at their base.

Fig. 3. Persistent calyx, surrounding the pistil.

Fig. 4. Capsule opening transversely near the base, exposing seeds and dissepiment.

Fig. 5. Dissepiment and 2 seeds, the upper part of the capsule being removed.

Fig. 6. Bilocular capsule cut transversely, showing 2 seeds in

each loculament.

Fig. 7. Roundish compressed seed.

Fig. 8. Seed cut longitudinally, showing the albumen with portions of the spirally-rolled-up embryo immersed in it.

Plate CXXVI. Solanum nigrum and Solanum Dulcamara, belong-

ing to the Nat. Ord. Solanaceæ.
Fig. 1. Solanum nigrum, Common Nightshade. Leaves ovate and wavy. Flowers in extra-axillary umbellate cymes.

Fig. 2. Solanum Dulcamars, Woody Nightshade or Bitter-sweet. Stem shrubby, leaves auricled, flowers in corymbose cymes opposite the leaves.

Fig. 3. Anther opening by 2 pores at its apex. Fig. 4. Transverse section of baccate fruit, showing 2 locula. ments, with seeds attached to a central placenta.

Bothnia.

Botany Bay Both.

Fig. 5. Coiled embryo with cotyledons and radicle.

Plate CXXVII. Atropa Belladonna, Common Dwale, Deadly Nightshade, belonging to the Nat. Ord. Atropaces. Large rhizome, giving off buds and roots. Leaves ovate, in pairs of unequal sizes, flowers solitary, drooping.

Fig. 1. Gamosepalous 5-partite calyx, and flower-bud.

Fig. 2. Campanulate corolla cut open, lobes unequal, 5 stamens, epicorolline, and distant above.

Fig. 3. Calyx and ovary.

Fig. 4. Transverse section of baccate fruit, with 2 loculaments and seeds attached to a central placenta.

Plate CXXVIII. Hyoscyamus niger, Common Henbane, belonging to the Nat. Ord. Atropaceæ. Leaves amplexicaul, sinuated, flowers nearly sessile, axillary, and unilateral.

Fig. 1. Calyx laid open, showing the pistil.

Fig. 2. Corolla laid open, showing reticulations, and stamens attached to it.

Fig. 3. Stamen, with anther opening by a longitudinal slit. Plate CXXIX. Digitalis purpurea, Purple Foxglove, belonging to the Nat. Ord. Scrophulariaceæ.

Fig. 1. Calyx in 5 deep segments, with the pistil. Fig. 2. Pistil separated.

Fig. 3. Didynamous stamens, with the anther-lobes continuous and dehiscent

Fig. 4. Didynamous stamens, with the anther-lobes collateral and unopened.

Fig. 5. Capsule cut transversely, showing two loculaments. Plate CXXX. Polygonum Bistorta, Common Bistort or Snakeweed, belonging to the Nat. Ord. Polygonaceæ. Leaves subcordateovate, waved, the radical ones with a winged footstalk, long ochreate stipules, flowers in a dense cylindrical racemose cyme, root large and tortuous.

Plate CXXXI. Myristica moschata, the nutmeg-tree, belonging to

the Nat. Ord. Myristicaceæ.

Fig. 1. Male plant (nat. size) with oblong nearly elliptical leaves, and flowers in axillary umbellate cymes.

Fig. 2. Perianth of male plant laid open to show the stamens with their united filaments.

Fig. 3. Anther, bilocular, and opening longitudinally.

Fig. 4. Female flower cut open, showing the single pistil, with short style and 2-lobed stigma.

Fig. 5. Young fruit.

Fig. 6. Ripe drupaceous fruit in the act of bursting, and showing the mace or arillode.

Fig. 7. Section of the ripe fruit, containing mace and seed

Fig. 8. The nut consisting of a hard endocarp inclosing the seed. Fig. 9. The oval seed.

Fig. 10. The seed cut vertically.

Fig. 11. Vertical section of endocarp and seed, showing ruminate albumen and the embryo.

Fig. 12. Embryo, showing 2 large foliaceous plicate cotyledons

Fig. 13. Embryo with radicle and cotyledons.

Plate CXXXII. Euphorbia hypericifolia, Tutsan-leaved Spurge, belonging to the Nat. Ord. Euphorbiaceæ.

Fig. 1. Plant (nat. size) with opposite oblong leaves, half heart-shaped at the base, and flowers in corymbose cymes

Fig. 2. Involucre with appendages, inclosing male and female

Fig. 3. Involucre cut open, to show the insertion of the numerous achlamydeous male monandrous flowers, and the single naked female flower, all pedicellated.

Fig. 4. Involucre deprived of its petaloid appendages, with female flower showing forked styles.

Fig. 5. Involucre inclosing the ripe fruit (regma).

Fig. 6. Stamen and anther dehiscing.

Fig. 7. Fruit with one of the cocci separated from the columella, and bursting to discharge the seed.

Fig. 8. Seed.

Fig. 9. Seed cut open longitudinally, showing fleshy albumen and inverted embryo.

Plate CXXXIII. Artocarpus incisa, the Bread-fruit tree, belonging to the Nat. Ord. Artocarpaceæ.

Fig. 1. Branch reduced to \(\frac{1}{3} \) its natural size, with cuneate-ovate leaves, lobed in a pinnatifid manner, male flowers in a clubshaped deciduous catkin, female flowers in rounded clusters.

Fig. 2. Transverse section of the male amentum with numerous flowers around the margin of a cellular receptacle.

Fig. 3. Male flowers, each formed by a single perianth. Fig. 4. Single male flower separated with a perianth in 2 segments and a single stamen.

Fig. 5. Cluster of female flowers.

Fig. 6. Single female flower separated, with ovary, style, and bifid stigma; the perianth is one piece with a contracted mouth.

Fig. 7. Ovary.

Fig. 8. Ovary laid open to show the ovule. Fig. 9. A variety of the ovary with 2 loculaments.

Fig. 10. Transverse section of a bilocular ovary.

Plate CXXXIV. Cycas circinalis. a species of false Sago-plant, belonging to the Nat. Ord. Cycadaceæ.

Fig. 1. Plant reduced to 12 its natural size. The stem or stipe is round and erect, the leaves pinnately-divided and forming a crown round the stem.

Fig. 2. Male amentum (nat. size), consisting of scales bearing on their under side 2-valved anthers.

Fig. 3. Upper side of one of the scales; it is somewhat triangular, tapering from apex to base, and terminating at the apex by a recurved point.

Fig. 4. Under side of a scale, bearing anthers.

Figs. 5, 6, and 7. Anther.

Fig. 8. Pollen magnified.

Plate CXXXV. Arum maculatum, Cuckow-pint, or Wake-Robin, belonging to the Nat. Ord. Araceæ.

Fig. 1. Flowering stalk, with hastate-sagittate spotted leaves, a spathe convolute at the base, inclosing a spadix bearing male and female flowers.

Fig. 2. Amylaceous corm, whence arise buds and roots.

Fig. 3. Berried fruit, after leaves and spadix have decayed, crowded into an oblong spike, which is of a bright scarlet colour. Plate CXXXVI. Plants belonging to the Nat. Ord. Fungi, the Mushroom order.

Fig. 1. Amanita muscaria, Fly Amanita, with a red warty pileus, and stipe surrounded by an annulus.

Figs. 2, 3, 4. Amanita verrucosa, Warty Amanita.

Figs. 5, 6. Agaricus semiglobatus, Glutinous Agaric. with a greenish-yellow, semiglobate pileus and an annulate stipe

Plate CXXXVII. Secale cereale, Rye, belonging to the Nat. Ord. Gramineæ.

Fig. 1. Culm, leaf, and spike of Rye.

Fig. 2. British specimen of Rye affected with Ergot. It is called Spurred Rye.

Fig. 3. Specimen of Ergotized Rye from East Florida.

Fig. 4. Spikelet of Rye, with subulate glumes, inclosing 2 or 3 florets, lower paleze with very long awns, upper bifid.

Fig. 5. Appearance presented by Ergot.

Fig. 6. Transverse section of Ergot, consisting of polygonal (J. H. B-R.) cells with oil globules.

BOTANY BAY, a spacious bay on the east coast of Australia, New South Wales, 5 miles south of Sydney, in Lat. 34. S. Long. 157. E. It was discovered by Captain Cook in 1770, and named from the profusion of then unknown plants found on its shores. The bay is about 5 miles in length and breadth, but the entrance is little more than a mile across. See Australia.

BOTARGA (a Spanish word), a kind of sausage prepared from the roe of the mullet. It is much used on the shores of the Mediterranean as a relish with wine.

BOTH, Jan and Andreas, Flemish painters, and pupils of Bloemart, were born at Utrecht about the year 1610. The union of these brothers was remarkable; they were

alike inseparable in their studies, their travels, and their painting. Jan painted the landscape part of their pictures in the manner of Claude Lorrain, and Andrew drew the figures and animals in the style of Bamboccio. They both died in 1650; Andrew having been drowned at Venice, his brother Jan, through grief, soon afterwards followed him to the grave. In the museum at Paris there are two pictures by these masters, one a View of Italy at Sunset, the other a Defile. The gallery at Dresden also contains two landscapes by these excellent artists.

BOTHNIA, a district on the north and west of the gult of the same name, belonging partly to Sweden, and partly to Russia. The rivers Muonio and Tornea separate SwedBottle.

Bothnia ish from Russian Bothnia, the former constituting the governments of Pitea and Umea, and the latter being included in the Russian government of Finland.

BOTHNIA, Gulf of. See BALTIC.

BOTHWELL, a village and parish of Scotland, county of Lanark, on the Clyde, 9 miles S.E. of Glasgow. In the vicinity are the remains of Bothwell Castle, and Bothwell Bridge, where a battle was fought on 22d June 1679 between the Covenanters and the royal forces, in which the former were defeated with great slaughter.

BOTHWELL, James Hepburn, Earl of. See Scotland. BOTRYOIDAL (βοτρύς and ἐιδός), having the form of a bunch of grapes.

BOTS. See ENTOMOLOGY, Index.

BOTTICELLI, Alessandro, an Italian painter, born at Florence in 1437, was a pupil of Filippo Lippi. He executed several pictures for Pope Sixtus IV. and for the city of Florence, for which he received large sums of money; but he expended all his acquisitions in thoughtless extravagance, and at last died in great distress aged seventy-eight. He was not only a painter, but a man of letters. Baldini, according to the general report, communicated to him the secret of engraving, then newly discovered by Finiguerra, their townsman. The famous edition of Dante's Inferno, printed at Florence by Niccolo Lorenzo della Magna in 1481, and to which, according to some authors, Botticelli undertook to write notes, was intended to have been ornamented with prints, one for each canto; and of these prints, as many as were finished were designed, if not engraved by Botticelli. It is remarkable that the first two plates only were printed upon the leaves of the book, and, for want of a blank space at the head of the first canto, the plate belonging to it is placed at the bottom of the page. Blank spaces are left for the rest, that as many of them as were finished might be pasted on. The first two, as usual, are printed on the leaves; while the others, seventeen in number, which follow regularly, are pasted on the blank spaces; and these, apparently, were all that Botticelli ever executed. About the year 1460 he is said to have engraved a set of plates, representing the Prophets and Sibyls. Basan tells us that he marked these plates with a monogram composed of the first two letters of the alphabet joined together.

BOTTLE. The first bottles were probably made of the skins of animals. In the Iliad (iii. 247), the attendants are represented as bearing wine for use in a bottle made of goat's skin, 'Αςκφ ἐν αἰγείφ' The ancient Egyptians used skins for this purpose, and from the language employed by Herodotus (ii. 121), it appears that a bottle was formed by sewing up the skin and leaving the projection of the leg and foot to serve as a cock; hence it was termed ποδεών. This aperture was closed with a plug or a string. Skin-bottles of various forms occur on Egyptian monuments. Greeks and Romans also were accustomed to use bottles made of skins; and in the southern parts of Europe they are still used for the transport of wine. The first clear notice of them in Scripture occurs in Joshua (ix. 4), where it is said that the Gibeonites took "old sacks upon their asses, and wine-bottles old and rent and bound up." Our Saviour's language is thus clearly explained: "Men do not put new wine into old bottles, else the bottles break." Skins are still most extensively used throughout Western Asia for water.

It is an error to represent bottles as being made exclusively of skins among the ancient Hebrews (Jones, Biblical Cyclopædia, sub voc.) The Egyptians possessed vases, bottles, &c., of hard stone, alabaster, glass, ivory, bone, porcelain, bronze, silver, or gold; and also, for the use of the people generally, of glazed pottery or common earthenware. As early as Thothmes III, assumed to be the Pharaoh of the Exodus, B.C. 1490, vases existed of a shape so elegant and of workmanship so superior, as to show that the art was

not, even then, in its infancy. The British Museum contains a fine collection of these articles. The process of making glass bottles is described under the head GLASS. Bottomry. Perhaps the largest manufactory of wine bottles in the world is at Folembray in France, which is said to produce no fewer than eight millions annually. See GLASS.

BOTTOM, in mercantile language, is a familiar expression for a ship; as in the phrase to ship goods in foreign

BOTTOMRY, a maritime contract, by which a ship (or bottom) is hypothecated in security for money borrowed for the purposes of her voyage, under the condition, that if the ship arrive at her port of destination, the borrower personally, as well as the ship, shall be liable for the repayment of the loan, together with such premium thereon as may have been agreed on; but that if the ship be lost, the lender shall have no claim against the borrower, either for the sum advanced, or for the premium. In consideration of the risk thus incurred by the lender, the premium (which is sometimes termed maritime interest) is usually high: it may range from ten to twenty-five per cent., or even more, according to the nature of the risk, or the difficulty of procuring the necessary funds. The freight may be pledged as well as the ship, and, if necessary, the cargo also. When money is borrowed on the security of the cargo, it is said to be taken up at respondentia, a term which seems to have been introduced from the circumstance of the borrower engaging to answer for the repayment of the loan on the arrival of the goods. But though the terms are distinctive, there is no essential difference in the nature of bottomry and respondentia contracts, and both are regulated by the same principles of maritime law. Indeed the contract of respondentia is now seldom or never entered into unless in conjunction with that of bottomry.

A bottomry contract may be written out in any form which sufficiently shows the conditions agreed on between the parties; but it is usually drawn up in the form of a bond. The document must show, either by express terms or from its general tenor, that the risk of loss is assumed by the lender; this being the consideration for which the high premium is conceded. The lender may transfer the bond by indorsation, in the same manner as a bill of exchange or bill of lading, and the right to recover its value becomes vested in the indorsees.

According to the law of this country, a bottomry contract remains in force so long as the ship exists in the form of a ship, whatever amount of damage she may have sustained. Consequently, the "constructive total loss" which is recognized in marine insurance, when the ship is damaged to such an extent that she is not worth repairing, is not recognized in reference to bottomry, and will not absolve the borrower from his obligation. But if the ship go to pieces, the borrower is freed from all liability under the bottomry contract; and the lender is not entitled to receive any share of the proceeds of such of the ship's stores or materials as may have been saved from the wreck. Money advanced on bottomry is not liable, in this country, for general average losses.

If the ship should deviate from the voyage for which the funds were advanced, her subsequent loss will not discharge the obligation of the borrower under the bottomry contract. If she should not proceed at all on her intended voyage, the lender is not entitled to recover the bottomry premium in addition to his advance, but only the ordinary rate of interest for the temporary loan. As the bottomry premium is presumed, in every case, to cover the risks in-curred by the lender, he is not entitled to charge the borrower with the premium which he may pay for insurance of the sum advanced, in addition to that stipulated in the bond.

The contract of bottomry seems to have arisen from the custom of permitting the master of a ship, when in a foreign country, to pledge the ship in order to raise money for repairs, or other extraordinary expenditures rendered necessary in the course of the voyage. Circumstances often arise, in which, without the exercise of this power on the part of the master, it would be impossible to provide means for accomplishing the voyage; and it is better that the master should have authority to burden the ship, and if necessary the freight and cargo also, in security for the money which has become requisite, than that the adventure should be defeated by inability to proceed. But the right of the master to pledge the ship or goods must always be created by necessity: if exercised without

Bottony

necessity the contract will be void. Accordingly the master of a British ship has no power to grant a bottomry bond at a British Bottrigari. port, or at any foreign port where he might have been able to raise funds on the personal credit of the shipowners. Neither has he any power to pledge the ship or goods for private debts of his own; but only for such supplies as are indispensable for the purposes of the

voyage.
The bottomry lender must use reasonable diligence to ascertain that a real necessity exists for the loan; but he is not bound to see to the application of the money advanced. If the lender have originally advanced the funds on the personal credit of the master or owners, or on any other security than that of bottomry, he is not entitled at a subsequent period to convert his claim into a bottomry obligation; and although the master should grant him such obligation, it would not bind the owners. In every case a bond procured

by compulsion would be void.

The power of the master to pledge the cargo depends upon there being some reasonable prospect of benefit to it by his so doing. He has no such power except in virtue of circumstances which may oblige him to assume the character of agent for the cargo, in the absence of any other party authorized to act on its behalf. Under ordinary circumstances he is not at liberty to pledge the cargo for repairs to the ship. If indeed the goods be of a perishable nature, and if it be impossible to get the ship repaired in sufficient time to obviate serious loss on them by delay, without including them under the bottomry contract, he has power to do so; because it may fairly be assumed, in the case supposed, that the cargo will be benefited by this procedure. But if there be time to communicate with the proprietors of the cargo, it is his duty to give them notice before resorting to this course. The general principle is, that the master must act for the cargo, with a reasonable view to the interests of its proprietors, under the whole circumstances of the case. he does this his proceedings will be sustained; but should he manifestly prejudice the interests of the cargo, by including it under bottomry for the mere purpose of relieving the ship, or of earning the freight, the owners of the cargo will not be bound by the bottomry contract. Any bottomry or respondentia bond may be good in part or bad in part, according as the master may have acted within or beyond the scope of his legitimate authority in granting it.

If two or more bottomry bonds have been granted at different stages of the voyage, and the value of the property be insufficient to discharge them all, the last dated bond has the priority of payment, as having furnished the means of preserving the ship, and thereby preventing the total loss of the security for the previous bonds.

In a recent case in the English Admiralty Court (the Cynthia, 20 L. 7, 54), it was decided that a bond granted by a British consul over a British ship, the master of which had been murdered in a mutiny by the crew, was valid, although the new master, appointed by the consul, had not been required to sign it.

When the sum due under a bottomry bond over ship, freight, and cargo, is not paid at the stipulated time, proceedings may be taken by the bondholder for recovery of the freight and for the sale of the ship; and should the proceeds of these be insufficient to discharge the claim, a judicial sale of the cargo may be resorted to. As a general rule the value of the ship and freight must be exhausted before recourse can be taken against the cargo.

The bottomry premium must be ultimately paid by the parties for whose especial benefit the advances were obtained, as ascertained on the final adjustment of the average expenditures at the port of

For further information on this subject, the reader is referred to the cases of the Gratitudine, 2 Rob. A. R. 240, 272; the Lochiel, 3 Rob. 34; the Alexander, 1 Rob. 346; to Soares v. Rahn, 3 E. F. Moore; Dobson v. Lyall, 8 Jurist 969; and especially to the cases of the Lord Cochrane, 8 Jurist 714, and of Jacobsen v. Reinhardt, 22 Scottish Jurist 309. BOTTONY. A cross bottony, in Heraldry, terminates at each end in three buds, knots, or buttons, resembling in some measure the three-leaved grass; whence, in Segoing's Trésor Heraldique it is termed croix trefflée. It is the

badge of the order of St Maurice.

BOTTRIGARI, ERCOLE, a mathematician eminently skilled in the science of music, was descended of a noble family of Bologna, and born in that city, A.D. 1531. With a strong predilection for the ancient music, he attempted, as Vincentino and others had done, to introduce the ancient scales into practice, but with no better success. He cor-

rected Gogavino's Latin version of Ptolemy in numberless instances, and to so good purpose, that Dr Wallis has in general conformed to it in his translation of that author. He Bouches du translated into Italian Boetius de Musica, with such parts of Plutarch and Macrobius as relate to music. He also made annotations upon Aristoxenus, Franchinus, Spataro, Vincentino, Zarlino, V. Galilei, and, in short, on almost every musical treatise he could obtain, as appears by the copies once belonging to him, which are now deposited in various libraries in Italy. Bottrigari's works contain greater proofs of his learning and skill in music than of his abilities as a writer, his style being remarkably inelegant. Nevertheless he affected the character of a poet, and left a collection of poems, printed in 1557, 8vo. Walther represents him as an able mathematician, and says that he was possessed of a very rich and valuable cabinet of curiosities which the emperor Ferdinand II. had a great desire to purchase. He died in 1612, and not in 1609 as stated by Mazzuchelli. Some of his works have been printed, and others are still

В

in manuscript. (Tiraboschi, vii.) BOTZEN, or BOLZANO (the ancient Pons Drusi), the capital of the circle of Etsch in Tyrol, is situated at the confluence of the Talfer and the Eisach, 32 miles N.N.E. of The town is well built in the Italian style, and has a fine old Gothic church, a castle, several churches and convents, and a gymnasium. Being intersected by roads from Italy, Germany, and Switzerland, it has an extensive transit trade, and four large annual fairs. It has also some manufactures of linen, silk, and hosiery goods, leather, &c. It is protected from sudden inundations by a strong dike of masonry nearly 2 miles in length, and in some parts 24 feet

thick. Pop. 9000.

BOUCHE OF COURT, the privilege of having meat and drink at court scot-free. This custom was anciently in use also in the houses of noblemen. Thomas earl of Lancaster retained Sir John de Ewre to serve him with ten men at arms in time of war, allowing them bouche of court, with livery of hay, oats, and horse-shoes. Sir Hugh Merril had the same privilege for life, on condition of serving King Edward II.

BOUCHES DU RHÔNE, a department in the S.E. of France, separated by the Durance from the department of Vaucluse on the north; and by the Rhône from that of Gard on the west: the Mediterranean bounds it on the south, and the department of Var on the east. Area 1,267,674 acres, of which above one-half is covered with wood and water, or is waste. The northern and eastern parts are covered with mountains, spurs of the Esterel and Alpine systems, the highest of which, Ste Victoire, is only 3420 feet above the level of the sea. In the W. and S.W. are the great alluvial plains of Crau and Camargue. The former of these, an immense tract of land lying between the Alps and the sea, is covered with boulders of all sizes, evidently the consequences of diluvial action. The Camargue is comprised within the delta of the Rhône, and is continually gaining upon the sea by the fresh deposits which that river is daily bringing down. Though portions of it are cultivated, the greater part is covered with marshes, ponds, and canals. Some of these ponds or lagoons are of great extent, particularly those of Valcarès and Berre. The first of these covers nearly the half of Camargue, and has no communication with the sea, while the latter extends between the most easterly arm of the Rhône and Marseilles, and discharges itself into the sea by a narrow passage called the canal de Martigues. The only canals in the department now navigable are the canal of Arles, 281 miles in length, extending from the town of that name to the Port de Bouc, and that of Craponne, connecting the Durance and the Rhône. In spring the climate is warm and dry; in summer the heat is intense, and is rarely mitigated by rain. In winter the mistral, a cold north

Boullers. wind from the high country of the Cevennes, sometimes prevails. The inhabitants cultivate with success the olive, vines, figs, almonds, capers, melons, and mulberries; while on the mountains there grow a variety of aromatic plants, such as thyme, lavender, absinthe, rosemary, and hyssop. The principal forest-trees are the oak and pine. A considerable quantity of potatoes is grown, but the supply of corn is quite insufficient to supply the demand. About one-thirteenth of the surface is covered with vineyards, producing annually 17,610,000 gallons of wine, of which a large proportion is exported. But the wealth of the department consists in its horses, cattle, and sheep. Of horses, it maintains about 10,000; of horned cattle, 4000; of sheep, from 400,000 to 500,000. These are distributed among a vast number of proprietors (25,000, according to some authorities), who, on the approach of summer, unite their flocks and drive them to the hilly regions in the north of the department. Another source of wealth is the produce of silk, which amounts annually to about 730,000 lb. The principal articles of manufacture are soap and soda; but there are also a few oil-mills, tanneries, coral-works, sugar-refineries, and silkmills. There are also several marble-quarries in the department; and the tunny, shad, and anchovy fisheries are valuable. Though the manufactures are not very important, the commerce of the department is extensive, as Marseilles has now for many years been the largest and wealthiest seaport in France. The public revenues amount to nearly two millions sterling, of which the customs produce more than a half.

The following is a table of the arrondissements, cantons, communes, and population of the department for 1851:-Arrondissements. Cantons. Communes. Population. Aix..... 10 59 112,026

This department has given birth to several distinguished men-Petronius the Latin poet, Tournefort and Adanson the naturalists, Puget the sculptor, Vanloo the painter, Massillon the pulpit orator, and the historians Thiers and

BOUFLERS, Louis François, Duke de, commonly called the Chevalier Bouflers, a peer and marshal of France, and a general of distinguished reputation, was born Jan. 10. 1644. Having early entered the army, he was raised in 1669 to the rank of colonel of dragoons. In the conquest of Lorraine he served under Marshal de Créquy. In Holland he served under Turenne, frequently distinguishing himself by his skill and bravery; and when that celehrated captain was killed by a cannon-shot in 1675, he commanded the rearguard during the retreat of the French army. After performing various military services in Germany, in Flanders, and on the frontiers of Spain, he was created, in 1690, general of the army of the Moselle, and contributed materially to the victory of Fleurus. In the following year he acted as lieutenant-general under the king in person; and whilst investing Mons, he was wounded in an attack on that place. He conducted the bombardment of Liège, although it was defended by an enemy superior in numbers, and afterwards forced the allied generals to abandon Luxembourg. He was intrusted with the command against King William at the siege of Namur; and for this and other important services he was raised, in 1693, to the rank of marshal of France. In 1694 he was appointed governor of French Flanders and of the town of Lisle. By a skilful manœuvre he threw himself into Namur in 1695, and held out with unexampled obstinacy against the army of the allies under King William, sustaining four assaults, and only surrendering the place after four months of open trenches and the loss of 20,000 men to the besiegers.

In the conferences which were held with the Earl of Port- Bougainland, and terminated in the peace of Ryswick, he had a principal share. During the following war, when Lisle was again threatened with a siege by the Duke of Marlborough and Prince Eugene, Bouffers was appointed to the command, and made an obstinate resistance of four months. His mag nanimity was not less remarkable than his military conduct; for when a partizan represented to him that it would not be difficult to kill Prince Eugene, he was told by the marshal that he might expect a great reward for taking him prisoner, but the severest punishment if anything were attempted against his life. He was rewarded and honoured by the king for his defence of Lisle, as if he had been victorious. It was indeed a species of triumph. His generous enemy, appreciating his merits, allowed him to dictate his own terms of capitulation: "Je signerai," said Prince Eugene, "tout ce que vous voudrez;" and he was as good as his word. When the affairs of France were threatened with the most urgent danger, Bouflers, though a senior officer to Villars, made an offer to serve under that general, and was with him at the battle of Malplaquet. Here he again displayed his military skill by conducting the retreat, so that he lost neither cannon nor prisoners. He died at Fontainbleau in 1711, leaving the character of a true patriot and a great commander.

BOUGAINVILLE, Louis Antoine de, a celebrated circumnavigator, was born at Paris in 1729. He was received advocate in the parliament of Paris, but soon abandoned the profession, and entered the army in the corps of musketeers. He associated much with Clairaut and D'Alembert, from whom he derived his knowledge of algebra and fluxions. At the age of twenty-five he published his treatise on the Integral Calculus, as a supplement and continuation of L'Hôpital's treatise Des infiniment petits. He was raised to the rank of major in the Picardy regiment. He went to London as secretary to the French embassy, and was chosen a member of the Royal Society. In 1756 he went to Canada as captain of dragoons, and aid-de-camp to the Marquis of Montcalm, and having distinguished himself in the war against England, was rewarded with the

cross of the order of St Louis.

After the peace, when the French government conceived. the project of colonizing the Malouines or Falkland Islands, Bougainville undertook to begin this establishment at his own expense. He began by landing some families of French Canadians; and the number of settlers was increased afterwards to 150. But this colony having excited the jealousy of the Spaniards, the French government agreed that it should be given up to them, on condition of their indemnifying Bougainville. Bougainville was then appointed to command the frigate La Boudeuse and the transport L'Etoile, on a voyage of discovery round the world. He set sail in November 1766, taking with him Commerçon as naturalist, and Verron as astronomer. This was the first voyage round the world performed by the French. Since the first circumnavigation by Magellan in 1519, and that of Drake in 1577, eleven other circumnavigations had been performed, part of them by the Dutch and part by the English. Having executed his commission of delivering up the Falkland Islands to the Spanish, Bougainville proceeded on his expedition, and touched at Buenos Ayres at the time of the expulsion of the Jesuits from Paraguay. Passing through the Straits of Magellan, he anchored for a week at Taheite, where the English navigator Wallis had touched eight months before. The numerous rocks and other dangers made him turn off to the N.E., and prevented him from continuing a westerly course, so as to pass through the channel which separates New Holland from New Guinea. In his general chart these two islands are laid down as one, although he possessed some information of the existence of the channel. Two years after, in 1770, Captain Cook sailed through thi: channel. The expedition having crossed all the meridians

Bougie.

Bougeant of the Pacific Ocean, and now suffering from scurvy, came to anchor in the Gulf of Cajeli in the island of Borou, one of the Moluccas, where the governor of the Dutch settlement liberally supplied their wants. As it was the beginning of September, the expedition shortened their stay at Borou, in order to take advantage of the latter part of the easterly monsoon, which carried them to Batavia. From thence they proceeded to the Isle of France, where Commercon remained, with the view of proceeding to examine the botany of Madagascar; as also did Verron for the purpose of observing the transit of Venus. In 1769 the expedition arrived at St Malo, after a voyage of two years and four months, with the loss of only seven out of upwards of 200 men.

Bougainville's account of the voyage (Paris 1771, 4to) is written with simplicity, and in a temper which inclined him to view objects on the humorous side. The art of making astronomical observations at sea was then much less perfect than now, and, accordingly, Bougainville's charts are found to be erroneous, particularly in the longitudes. After an interval of several years, he again received a naval command and saw much active service between 1779 and 1782. In the memorable engagement of April 12. 1782, in which Rodney defeated the Count de Grasse, Bougainville, who commanded the Auguste, succeeded in rallying eight ships of his own division, and bringing them safely into St Eustace. After the peace he returned to Paris, and solicited and obtained the place of associate of the Academy. He had a project of making a voyage of discovery towards the north pole. As this did not meet with support from the French government, he sent his plan to Admiral Phipps. Phipps, however, followed a different course, but only reached the 80th degree of north latitude.

Bougainville obtained the rank of vice-admiral in 1791; and in 1792, having escaped almost miraculously from the massacres of Paris, he retired to his estate in Normandy. He was chosen a member of the Institute at its first formation, and, in consequence, returned to Paris. He succeeded Borda as member of the Board of Longitude. In his old age, under the government of Napoleon, he enjoyed the dignity of senator, and was created a count and member of the Legion of Honour.

Retaining his good-humoured liveliness and his mental faculties to the last, he died in 1814, aged eighty-five. He was married, and had three sons who served in the French army. His éloge is written by Delambre, in the Memoirs of the Institute.

BOUGEANT, GUILLAUME HYACINTHE, a famous Jesuit, born at Quimper, Nov. 4.1690. He first taught humanity at Caen and Nevers, and afterwards settled in Paris at the college of Louis le Grand. He is the author of several works, written in his native language. The principal of these are, A Collection of Physical Observations, extracted from the best authors, 1719 and 1721, 4 vols. 12mo; A History of the Wars and Negociations which preceded the treaty of Westphalia, 2 vols. 12mo; A History of the treaty of Westphalia; The Female Doctor, or Distaff Theology, 12mo; Philosophical amusement on the Language of Beasts, Paris, 1739, 12mo; The Marvellous Voyage of Prince Fanferedin, Paris, 1735, 12mo; Exposition of the Christian Doctrine; and Anacreon and Sappho, a dialogue in Greek verse. He died January 7. 1743.

BOUGIAH. See BUGIAH.

BOUGIE (French bougie, a candle), a long cylindrical surgical instruments for dilating the urethra, the rectum, or the esophagus, in cases of stricture. Bougies vary as to their materials, size, and shape, and are solid or hollow, stiff or flexible, according to their particular use. Some bougies are of steel, silver, &c.; others are made of slips of waxed linen rolled cylindrically, or by covering a fine cord of flax or silk with successive coatings of linseed-oil, inspissated by boiling, and rendered drying by litharge; after which, they are

smoothed by rolling on a slab, and then polished. The Bouguer. best elastic bougies are made of caoutchouc dissolved in a mixture of drying linseed-oil and turpentine; or, still better, of caoutchouc dissolved in sulphuric ether. Medicated bougies also are employed in surgery.

BOUGUER, PIERRE, an eminent French mathematician, was born in 1698. His father, one of the best hydrographers of his time, was regius professor of hydrography at Croisic in Lower Brittany, and author of an excellent treatise on navigation. Young Bouguer was bred to mathematics from his infancy, and at an early age was appointed to succeed his father as professor of hydrography. In 1727 he gained the prize given by the Academy of Sciences for his paper "On the best manner of forming and distributing the Masts of Ships;" and two other prizes, one for his dissertation "On the best method of observing the Altitude of Stars at Sea;" the other for his paper "On the best method of observing the Variation of the Compass at Sea." These are published in the Prix de l'Académie des Sciences. In 1729 he published Essai d'Optique sur la Gradation de la Lumière, the object of which is to define the quantity of light lost by passing through a given extent of the atmosphere. He found the light of the sun to be 300 times more intense than that of the moon. He was soon after made professor of hydrography at Havre; and succeeded Maupertius as associate geometer of the Academy of Sciences. He was afterwards promoted in the academy to the place of pensioned astronomer, and went to reside in Paris.

It was resolved to send an expedition to South America for the purpose of measuring a degree of the meridian near the equator. From that measurement, compared with the length of a degree of the meridian in other latitudes, the deviation from sphericity in the figure of the earth might be known. The academy made choice of four of its members to proceed on this voyage. These were Godin, Bouguer, and De la Condamine, for the geodetical operation, and the younger Jussieu as naturalist. They sailed from La Rochelle in 1735, and it was ten years before Bouguer returned to France. The account of his operations during the expedition is given by him in the Memoirs of the Academy of Sciences, 1744, and in a separate work entitled La Figure de la Terre determinée par les Observations de MM. Bouguer et De la Condamine. There is likewise an account of this expedition published by Don George Juan and Don Antonio de Ulloa, two scientific officers of the Spanish navy, who accompanied the expedition. The length of a portion of the meridian was measured on the ground by means of a base and a set of triangles. Then, by observing the altitude of the s of Orion which passed near the zenith simultaneously at the two ends of the meridian line that had been measured, that line was found to contain 3° 7' of latitude. A star near the zenith was employed, that the observation might not be affected by refraction; s of Orion passed the meridian in the zenith near the middle of the line measured, so that the distance of that star south of the zenith of the northern extremity of the line was 1° 25' 46"; and its distance north of the zenith of the southern extremity of the line was 1° 41' 13", the sum of these two numbers making 3° 7′. The altitude was taken by zenith sectors of a long radius. The ground on which these operations were performed was 12,000 feet above the level of the sea, and 4200 feet above the neighbouring city of Quito, and situate in a plain extending from north to south, between the two ridges of the Cordil-The northern extremity of the arc was on the equator. The length of the degree resulting was 56,767 toises; but this was the degree of a curve circumscribed round the earth at the height of 12,000 feet above the level of the sea; and the length of the degree at the level of the sea deduced from this, with some other corrections, is 56,753 toises. This length of the degree of the meridian at the equator was compared with the degree of the meridian measured in France, with the degree measured in Lapland, and with the degree of longitude deduced in the south of France. From this comparison it was concluded that the equatorial diameter of the earth is to the polar diameter as 179 to 178, and that the equatorial radius of the earth was about eight leagues longer than the polar. Since the time of Bouguer, degrees have been measured in different climates with more accurate instruments than he possessed; but the precise proportion of the equatorial and polar diameters of the earth is not yet finally ascertained. Bouguer makes the excess of the equatorial diameter above the polar to be 17; Sir Isaac Newton made it 128; Laplace, calculating from the lunar motion, 312; Melanderhielm and Svanberg, from a degree measured anew in

Bouhours. Lapland in 1783, compared with the degree measured in the province of Quito, 313. Bouguer found the seconds pendulum 36 of a line shorter at the summit of Pichincha than at the level of the sea; that is, the force of gravity was less by a 1200th part at that elevation.

Bouguer also made observations on the limit of perpetual snow, a subject which has been elucidated since his time by the researches of Humboldt. Von Buch, Wahlenberg, and others. Whilst at the of Humboldt, Von Buch, Wahlenberg, and others. equator, he made observations to ascertain the obliquity of the ecliptic, which he found to be 23° 28' 28". He also made some experiments on the deviation of the plumb-line from the vertical, occasioned by the attraction of a neighbouring mountain—a phenomenon afterwards investigated by Dr Maskelyne on the mountain

The number of Bouguer's papers contained in the printed Memoirs of the Academy of Sciences, is a sufficient proof of his great mounts of the Interest of his most valuable inventions, the Heliometer, an instrument for calculating very acute angles with extreme precision, and applied to the determination of the diameters of stars, and their distances from the earth, is described in the Memoirs for 1748. See Heliometer. Some experimenters maintained that the plumbline had a diurnal oscillation; Bouguer showed that it remains at rest. He employed for this purpose a telescope, attached to the end of a chain 187 feet long, suspended within the dome of the Invalides at Paris: the telescope was directed to a distant mark, so that any motion in this long pendulous system might be seen by the deviation of the wires of the telescope from the mark. The particulars of this experiment are to be found in the Mém. de l'Academie des Sciences, 1754. In the volume for 1739 and 1749 there are papers of his on the astronomical refraction in the torrid zone, particularly in cases where the star is seen at more than 90° from the zenith, in consequence of the observer being in a high situation. In the volume for 1747, he proposed a log of a new construction for measuring a ship's way. In the same collection there are papers of his on the length of the pendulum, on the form of the prow which suffers least resistance in passing through the water, and on a variety of other subjects. Bouguer died in 1758, aged sixty. His disposition was naturally mild, and the dissensions that arose between him and his fellow traveller De la Condamine caused him great vexation. By economy he had acquired a moderate fortune, a part of which he bequeathed to the poor.

The following is a list of his principal works:—Traité d'Optique sur la Gradation de la Lumière, 1729 and 1760. Entretiens sur la Cause d'Inclinaison des Orbites des Planètes, 1734. Traité de Navire, &c., 1746, 4to. La Figure de la Terre determinée &c., 1749, 4to. Nouveau Traité de Navigation, contenant la Théorie et la Pratique du Pilotage, 1753. Solution des Principaux Problemes sur la Manœuvre des Vaisseaux, 1757. Opérations jaites pour la Verification du Degré du Méridien entre Paris et Amiens; par Mess. Bou-

guer, Camus, Cassini, et Pingré, 1757.

After his return from South America he was editor of the Journal des Savans. His éloge is contained in the Memoirs of the Academy of Sciences for 1758.

BOUHOURS, DOMINIQUE, a celebrated French critic, born at Paris in 1628. He entered into the society of Jesuits at the age of sixteen, and was appointed to read lectures upon polite literature in the college of Clermont at Paris, and on rhetoric at Tours. He afterwards became preceptor to the two sons of the Duke of Longueville. The duke died in Bouhours' arms; and the "account of the pious and Christian death" of this great personage was his first publication. He was sent to Dunkerque to the Popish refugees from England; and in the midst of his missionary occupations published several books. Among these were Entretiens d'Ariste et d'Eugène, a work of a critical nature on the French language, printed five times at Paris, twice at Grenoble, and afterwards at Lyons, Brussels, Amsterdam, Leyden, &c. It embroiled him in numerous quarrels, particularly with Menage, who, however, lived in friendship with the author before and after. The fame and merit of this piece recommended Bouhours so effectually to the great Colbert, that he intrusted him with the education of his son the Marquis of Seignelay. He afterwards wrote several other works in French, the chief of which are, Remarks and Doubts upon the French Language, 1694; Dialogues upon the art of Thinking Well in works of Genius, 1687; The Life of St Ignatius, 1679; The Art of Pleasing in Conversation; The Life of St Francis Xarier, 1682. It was his practice to publish alternately a

book on literature and a work on some subject of piety, Boulainwhich gave occasion to a wag, in a satirical epitaph, to remark of him, "qu'il servait le monde et le ciel par semestre." His Pensées ingenieuses des Anciens et des Modernes, Boulanger though at once instructive and amusing, exposed him to censure as well as ridicule, on account of some strange misjudgments and omissions. He has classed Boileau with the least esteemed of the Italian satirical versifiers; and what is still more remarkable, he has omitted, in his Thoughts on the Moderns, all mention of Pascal. That a disciple of St Ignatius should wish to forget the author of the Provincial Letters is, however, not to be wondered at. Among the numerous epigrams to which this omission gave rise is the following by Madame Deshoulières:

> Père Bouhours, dans vos Pensées, La plupart fort embarrassées, A moi vous n'avez point pensé. Dans cette liste triomphante Des célèbres auteurs que votre livre chante, Je ne vois point mon nom placé; Mais aussi dans le même rôle Vous avez oublié Pascal, Qui pourtant ne pensait mal: Un tel compagnon me console.

BOULAINVILLIERS, HENRI DE, Lord of St Saire, an eminent French writer, descended from a very ancient and noble family, was born at St Saire in Normandy A.D. 1658. He received his education at the college of Juilli, where he early discovered the uncommon abilities for which he was afterwards distinguished. His historical writings are numerous and important, but deformed by an extravagant admiration of the feudal system, which he regarded as the chef d'æurre of the human mind. He misses no opportunity of regretting those "good old times," when the people were enslaved by a few petty tyrants alike ignorant and barbarous. His principal works are his Histoire de l'Ancien Gouvernment de la France, &c., La Haye, 1727, 3 tom. 8vo ; Etat de la France ; avec des Mémoires sur l'Ancien Gouvernment, &c., Lond. 1727, 3 tom. fol.; Histoire de la Pairie de France, &c., Lond. 1753; La Vie de Mahomet (a Fable of Mahomet, as Mosheim calls it); Histoire des Arabes, Amst. (Paris), 1731, 2 vols. 12mo. All his works were published after his death. His philosophical writings have now lost all their value. His professed refutation of the system of Spinoza is in fact a weak and imperfect exposition of that writer's opinions. He died at Paris in 1722

BOULANGER, JEAN, a French engraver, born at Amiens in 1607. If not the inventor, he had at least the merit of improving the art of stippling. His works are after Raphaël, Lionardo da Vinci, Mignard, &c. Sometimes the naked parts of his figures are not correctly drawn nor in good taste. His best prints, however, are deservedly held in considerable esteem.

Boullanger, Nicolas-Antoine, a man whose name and writings have been much cited by the literary infidels of France, was the son of a tradesman at Paris, where he was born in 1722. He studied in the college of Beauvais, but his progress while there was unusually slow. Having, however, a talent for mathematics, he soon acquired so much knowledge of that science, that he was appointed to accompany the Baron de Thiers to the army in the capacity of engineer. He thus became concerned in various works which brought under his observation a number of geological facts which, he thought, evinced the great antiquity of the earth, and a long series of revolutions which it must have undergone. Proceeding to speculate upon the moral influence of these disastrous phenomena, he found it necessary to apply to the study of ancient literature, and he acquired some knowledge of Hebrew, Syriac, Chaldaic, and Arabic; but his studies were interrupted by his death at the early age of thirty-seven. He was the author of L'Antiquité De-

Boulangerite Boulognesur-Mer.

voilée par ses Usages, a posthumous work, published by the Baron d'Holbach in 1766, and which excited considerable attention about the end of that century. This work, though not devoid of eloquence, and displaying a powerful imagination, exhibits at the same time deficiencies of judgment and critical acuteness. He furnished to the Encyclopédie the articles Déluge, Corvée, Guèbres, Langue Hibrarque, and Économie Politique. His collected works were published at Paris in 1792, 8 vols. 8vo, and at Amsterdam in 1794, 6 vols. 8vo. He is said to have possessed a mild and engaging disposition; but it is difficult to reconcile this statement with the dark and impetuous spirit which animated him as a writer. Latterly he was connected with a class of men, illustrious indeed in point of talent, but who were the professed enemies of religion, and were heated with the delusive idea of effecting its destruction. Boulanger contributed his share to this unworthy enterprise, by arguments which he drew from his studies, and the hypotheses he had conceived. It ought to be observed, however, that several of the irreligious writings which have been ascribed to him are spurious.

BOULANGERITE, a sulphuret of lead and antimony, found at Molières, in the department of the Gard in France. and near Nerlschink in Siberia, &c. It consists of 55.57 lead, 24.60 antimony, and 18.86 sulphur, with accidental quantities of arsenic and iron.

BOULAY, CESAR ÉGASSE DU (in Latin Bulæus), was born at St Ellier (Mayenne), in the beginning of the seventeenth century. He became successively professor of humanity at the college of Navarre, register, rector, and historiographer of the university of Paris. He died in 1678. Of his works the principal are, a History of the University of Paris, in Latin, 6 vols. folio, 1665 and 1673; and the Thesaurus of Roman Antiquities, 1651, folio.

BOULDER, a name given to any rounded mass of stone worn smooth by the action of water. See Geology. Boulder Formation, or Diluvial Formation, consists of sand, clay, gravel, &c., mixed with water-worn stones of different sizes; and in Scotland is called Till.

BOULOGNE-SUR-MER, a town of France, in the department of the Pas de Calais, the capital of a canton and arrondissement of the same name. It is situated on the sea-shore at the mouth of the Liane, in 50. 44. N. Lat. 1. 36. E. Long., 166 miles from Paris by railway. It was known to the Romans under the name of Gessoriacum, and was afterwards called Bononia, from the name of a fort built at the beginning of the Christian era on the opposite bank of the Liane. A bridge was thrown across the river, and Caligula erected on its northern bank a lighthouse which attracted first the fishermen, and ultimately the entire population of Gessoriacum. During the middle ages the town was frequently besieged. In 882 it was taken and sacked by the Norman pirates. In later times it was assailed, but without success, by Henry III. of England. In 1544 it was taken by Henry VIII. after a siege of six weeks; but five years after it was restored to France by Edward VI. for the sum of 40,000 livres. Boulogne consists of two parts, the High or Old Town, and the Low or New Town. The Old Town, situated on the top of the hill, still boasts its ancient ramparts and arched gateways. The citadel, flanked by high towers, and separated from the town by a fosse, has been recently converted into a barrack. In the middle of the old town is the Hôtel de Ville, behind which is the ancient beffroi or belfry. A cathedral has been in course of erection since 1827, and in the immediate neighbourhood are several nunneries. The New Town or basse-ville, extends from the foot of the hill to the harbour and along the shore, and is the chief seat of commerce. The only public building of importance is the museum, which is said to contain one of the best provincial collections in France. tached to it is a public library of 22,000 volumes, and 3000 MSS., many of them very rare and richly illuminated. The Boulter. present entrance to the harbour, in which the tides rise from 17 to 28 feet, was formed in 1829. It is flanked on both sides with wooden piers, which in fine weather are the favourite promenades of the inhabitants. It is calculated that from 100,000 to 150,000 passengers annually land here. On one side of the harbour is the basin formed by Napoleon for the flotilla of flat-bottomed boats, which was intended to convey his troops to the English shores at the time of the projected invasion. On a hill at a short distance from the town is a marble monument, erected by the grande armée in commemoration of this event, 164 feet in height, surmounted by a statue of the emperor, by Bosio, 16 feet high. Boulogne possesses 1300 vessels, all engaged in the fisheries. The fish taken, consisting chiefly of herrings, mackerel, whiting, turbot, cod, and oysters, are transmitted in large quantities to Paris by railway, but there is always an abundant and cheap supply reserved for the town itself. Government makes provision for the widows and families of fishermen accidentally drowned. In 1848, 1158 steamers entered the harbour of Boulogne; and 1149 left it. Pop. in 1821, 16,607; in 1851, 29,488, of whom nearly 7000 are English. Boulogne has two English chapels, and upwards of a hundred boarding schools, many of them managed by Englishmen. The arrondissement of the same name comprises 6 cantons, 100 communes; pop. (1851) 117,615. The house in which Le Sage died is still to be seen at No. 3 Rue de Chateau. John Wilkes lived here for some time in voluntary exile, and the poet Churchill is buried in the cemetery. Thomas Campbell, whose house is still pointed out to the

stranger, died here in 1843.

BÖULTER, HUGH, D.D., an eminent English prelate, was born in or near London, January, 4. 1671. He was educated at Merchant Tailors' School, whence he removed to Christ Church, Oxford; and some time after was elected a demy of Magdalen College at the same time with Addison and Wilcox. In 1700 he was made chaplain to Sir Charles Hodges, secretary of state; and soon afterwards was preferred to the rectory of St Olave, Southwark, and the archdeaconry of Surrey. In 1719 he attended George I. to Hanover as his chaplain. The king appointed him English tutor to Prince Frederick; and rewarded his services by making him dean of Christ Church and bishop of Bristol in the same year. About four years after he was nominated to the archbishopric of Armagh; the alarming discontent existing at the time in Ireland having suggested the wisdom of having in the primacy a man whose judgment and moderation would contribute to the preservation of tranquillity. Boulter at first declined the office, but the urgent command of the king finally overcame his reluctance, and he arrived in Ireland in November 1724. He at once devoted himself with zeal and energy to the promotion of the welfare of that country; and his noble acts of public spirit and beneficence did much to alleviate the national distress. In seasons of great scarcity he was more than once instrumental in preventing an impending famine; and on one of these occasions he distributed vast quantities of corn throughout the kingdom, for which he received the thanks of the House of Commons. At another time 2500 persons were fed at the poor-house in Dublin every morning, and as many every evening, for a considerable time, mostly at his own expense. Every measure of public improvement received his hearty co-operation. He was a true friend to the poor clergy of his diocese, and maintained several of their children in the university. He erected four houses at Drogheda for the reception of clergymen's widows, and purchased an estate to endow them. His charities for augmenting small livings and buying glebes amounted to upwards of L.30,000, besides what he devised by will for similar purposes in England. In short, the instances of his generosity and benevolence, his virtue, piety, and wisdom, are almost innu-

Bounty

Bourbon.

Boultine merable, and the history of his life is his noblest panegyric. This excellent prelate died at London, June 2. 1742, and was interred in Westminster-abbey, where a beautiful monument was erected to his memory.

BOULTINE, a term among workmen for a moulding, the convexity of which is just one-fourth of a circle. It is the member just below the plinth in the Tuscan and Doric capitals.

BOULTON, MATTHEW, a manufacturer and practical engineer of great celebrity, was born at Birmingham on the 14th of September 1728. He was educated at a neighbouring grammar-school, kept by Mr Anstead of Deritend, and was called early into active life upon the death of his father in 1745. The various processes by which the powers of the human mind have given facility to the artist in rendering the different forms of matter obedient to his command, afforded ample scope for the exercise of his inventive faculties, in improving the manufactures of his native place. His first attempt was a new mode of inlaying steel; and he succeeded in obtaining a considerable demand for the products of his manufactory, which were principally exported to the Continent, and not uncommonly re-imported for domestic use as of foreign manufacture.

In 1762, his fortune being already considerable, he purchased a tract of barren heath in the neighbourhood of Birmingham, with a single house on it, and there founded, at the expense of L.9000, the manufactory which has been so flourishing, and so well known under the name of Soho. His workmen were at first principally employed in the imitation of or-moulu, and in copying oil paintings with great accuracy, by means of a mechanical process which was invented by a Mr Eggington who afterwards distinguished himself by various works in stained glass. Boulton finding the force of horses inadequate to the various purposes of his machinery, erected in 1767 a steam-engine, upon the original construction of Savery; which, notwithstanding the inconvenience of a great loss of steam from condensation, by its immediate contact with the water raised, has still some advantages from the simplicity of the apparatus which it requires, and has even lately been found to succeed well upon a small scale. But Boulton's objects required a still more powerful machine, and he had the discernment to perceive that they might be very completely attained by the adoption of the various improvements lately made in the steamengine by James Watt of Glasgow, who had obtained a patent for them in 1769, the privileges of which were extended in 1775, by an act of parliament, to a term of 25 years. Boulton induced this ingenious and scientific inventor to remove to Birmingham. They commenced a partnership in business, and established a manufactory of steam-engines, in which accurate execution kept pace so well with judicious design, that its productions continued to be equally in request with the public after the expiration of the term of that legal privilege which at first gave the proprietors the exclusive right of supplying them, and which had been confirmed in 1792 by a decision of the Court of King's Bench against some encroachments on the right of the patentee. It was principally for the purpose of carrying on this manufactory with greater convenience, that the proprietors established an iron-foundry of their own at Smethwick, in the neighbourhood of Soho.

In 1785 Boulton was made a fellow of the Royal Society, about the same time with Withering, and several others of his scientific neighbours. In 1788 he turned his attention to the subject of coining, and erected machinery for the purpose, so extensive and complete, that the operation was performed with equal economy and precision, and the coins could not be imitated by any single artist for their nominal value; each of the stamps coining, with the attendance of a little boy only, about eighty pieces in a minute. The preparatory operation of laminating and cutting out the metal

is performed in an adjoining room; and all personal communication between the workmen is rendered unnecessary by the mechanical conveyance of the work from one part of the machinery to another. A coinage of silver was executed at this mint for the Sierra Leone Company, and another of copper for the East Indies, besides the pence and half-pence at present in circulation throughout England, and a large quantity of money of all kinds for Russia. In acknowledgment of Boulton's services, and in return for some specimens of his different manufactures, the Emperor Paul made him a present of a valuable collection of medals and minerals.

In 1797 he obtained a patent for a mode of raising water by impulse, the specification of which is published in the ninth volume of the Repertory of Arts, p. 145. It had been demonstrated by Daniel Bernoulli, in the beginning of the last century, that water flowing through a pipe, and arriving at a part in which the pipe is suddenly contracted, would have its velocity at first very greatly increased; but no practical application of the principle appears to have been attempted, until an apparatus was set up in 1792 by Mr Whitehurst, for Mr Egerton of Oulton, in Cheshire, consisting of an air-vessel, communicating with a water-pipe by a valve, which was forced open by the pressure or rather impulse of the water, when its passage through the pipe was suddenly stopped by turning the cock in the ordinary course of domestic economy; and although the pipe through which the water was forced up was of moderate height, the airvessel, which was at first made of lead, was soon burst by the "momentous force," as Mr Whitehurst very properly terms it. The apparatus had excited much attention in France, under the name of Montgolfier's hydraulic ram; and Boulton added to it a number of ingenious modifications, some of which, however, are more calculated to display the vivid imagination of a projector, than the sound judgment of a practical engineer, which had in general so strongly characterized all his productions.

He died, August 17. 1809, after a long illness, in possession of considerable affluence and of universal esteem. (Monthly Magazine, October 1809, p. 368).

BOUNTY, in Commerce, a premium paid by government for the encouragement of any branch of industry. See POLITICAL ECONOMY. It also denotes a premium offered to induce men to enlist in the public service.

BOURBON, the name of one branch of the Capet family, which has given kings to France from 1589 to our own times. This branch succeeded the House of Valois on the throne. It derives its origin from Robert, youngest son of Louis IX. See France.

BOURBON, Charles, Duke of, and constable of France, was born A.D. 1489. He was the son of Gilbert, Count of Montpensier, and of Clara, daughter to Federigo Gonzaga, Marquis of Mantua. As a statesman and a warrior, he eclipsed all the princes of France of his time; and the simplicity and gentleness of his manners made him the idol of the soldiery. By Francis I. he was made constable of France when only twenty-six years of age, and he gave abundant evidence that this honour was not undeserved. As viceroy of the Milanese he made himself universally popular, and his warlike prowess was particularly displayed at the great battle of Marignano, where he fought by the side of the illustrious Bayard. Having become embroiled, however, in a legal suit with the queen-mother respecting some very large estates, part of which he held in right of his deceased wife, Suzanne de Bourbon, by an iniquitous decision his estates were sequestrated. Duchess d'Angoulême is believed to have been instigated to this act of revenge by his coldness in slighting her addresses. Charles of Bourbon, in indignation, entered into the service of Charles V., and made himself master of the whole Milanese. He then led the emperor's troops against Rome; but while in the act of placing a scaling-ladder

History.

Bourbon. against the walls, he was killed by a random shot, May 6, J 1527.

> Bourbon (Borbonius), Nicolas, a Latin poet, born in 1503 at Vandeuvre, near Bar-sur-Aube, was the son of a master blacksmith. Margaret de Valois appointed him preceptor to her daughter, Jeanne d'Albret of Navarre, mother of Henri IV. After residing several years at court he retired to Candé, where he had a benefice. He died about 1550. He wrote eight books of Nuga; a poem on the forge, entitled Ferraria; De Puerorum moribus, &c. Erasmus praises his Nugæ. Scaliger, however, speaks of him with contempt.

> BOURBON, Nicolas, one of the best Latin poets France has produced, grand-nephew to the preceding, was born in 1574. He was professor of eloquence in the Royal College, canon of Langres, and one of the forty of the French Academy. At length he retired to the house of the fathers of the Oratory, where he died in 1644. His poems were printed at Paris in 1651, 12mo. His chef d'œuvre is a poem on the assassination of Henri IV., entitled Diræ in Parricidam. Modern criticism, however, is not very favourable to it.

> Bourbon, Isle of, an island in the Indian Ocean, belonging to France, about 400 miles E. of Madagascar and 90

> miles W.S.W. of Mauritius, in Lat. 21. 30. S. Long. 55. 30.

E. It was discovered in 1545 by Mascarenhas, a Portuguese navigator, whose name it originally bore. It remained uninhabited till 1646, when De Prony, the French commandant of Madagascar, formally took possession of it in the name of his sovereign, and gave it the name of Bourbon. It was at first employed only as a penal settlement; but in 1654 De Hacourt, a director of the French East India Company, established a small settlement, which, however, never prospered, and the colonists, becoming disheartened, embarked for Madras in an English vessel

which happened to touch at the island. It was unvisited save by pirates and buccaneers, till a remnant of the French who had escaped the massacre of their countrymen in Madagascar took refuge in the island, and, with the crew of a privateer, which happened to be wrecked on the shore, formed a colony, which in a short time began to prosper. In 1661 it was made over by Louis XIV. to the East India Company, who sent out small relays of workmen from time to time. In 1710 a regular administration was organized,

and a governor despatched from France. The council by

which he was assisted comprised the principal officials of the government, and was subject in appeal cases to the sovereign council of Pondicherry. Two years after, the new settlement was strong enough to take possession of the Mauritius, which had been abandoned by the Dutch, and in 1732 the seat of government was removed to that island. In 1735 the governor, La Bourdonnais, fortified Bourbon

with such skill that an English fleet under Boscawen attempted in vain to take possession of it. At the outbreak of the French Revolution the home government abolished slavery in all their dominions, but the people of Bourbon, much of whose wealth consisted of slaves, refused to obey

orders, and deposed their governor, though they still acknowledged the authority of the mother country. From 1790 to 1795, the principles of the Revolution continued to gain ground; but at the latter date a reaction took place, and, in 1799, 7108 proprietors, who had countenanced these

principles, were banished to the Séchelles. The ship in which they sailed was attacked by an English frigate, and the whole ship's company was shot or drowned. Till 1803 Bourbon, which under the republic had assumed the title of Ile de la Réunion, was self-governed. In that year

Napoleon sent out a governor, and in 1806 the island once more changed its name, and became the Ile Bonaparte. In 1810, after a gallant resistance, it fell into the hands of the English, who retained it till the general peace of 1814,

when the island resumed its old name of Bourbon. In the Bourbon. following year, before the downfall of Napoleon, it was once more besieged by the English, and along with the Mauritius again fell into their hands. After the general pacification of Europe Bourbon was restored to France, in whose possession it now is, but the adjoining island has since been retained by its English conquerors. In April 1848 a decree of the National Assembly abolished slavery in all the French dominions, and an indemnity of nearly L.5,000,000 sterling was awarded to the slaveholders of Martinique, Guadaloupe, and Bourbon, which in this year once more changed its name for the old one of La Réunion. It was ordained, however, that a year should elapse between the

passing of the act and the manumission of the slaves. In 1852 the last instalment of the indemnity was paid.

Bourbon, which is nearly elliptical in form, measures 40 miles at Physical its greatest length, 27 at its greatest breadth, and, following the aspect.

windings of the shore, 104 miles in circumference. The whole island is, as it were, one mountain, having its highest point in the centre, and sloping thence gradually to the sea. This great mass, however, is split into two systems. In the northern range is the Piton des Neiges, the highest peak in the island, about 10,000 feet above the level of the sea. Of the southern system the highest point is the Piton de Fournaise, an active volcano, 7000 feet high. The northern parts of the island present every indication of having been at one time subject to volcanic action of the most violent kind; but the operation of nature and the industry of man have long since converted these once desert plains into beautiful and fertile fields. In the south-east, however, the state of matters is quite different. The scarcity of water, and the vicinity of the volcano, which is the most active in the world, bursting forth at least twice every year, and sending its lava streams sometimes as far as the sea, combine to make this portion of the island the exact antithesis of the other. One portion of it, known as the Pays Brûlé, comprising 11,543 acres, is a desert waste, untenanted by man or beast. Between the two mountain systems are the Plaine des Cafres and the Plaine des Palmistes. The first of these, sloping to the south, exhibits no signs of vegetation except a few stunted shrubs, while the latter, sloping to the north, is watered by numerous streams and is remarkably fertile. Both are at a considerable elevation above the sea. In the centre of the island is a lake, called the Grand Etang, which, though it derives its waters only from the rain, is half a mile in diameter, and in winter 30 feet deep. It has no outlet, yet in summer the evaporation is so great that it is sometimes nearly dried up. The rocky and mountainous nature of the entire island precludes the existence of deep or navigable streams. Such as it possesses are merely mountain torrents, reaching the sea by a succession of waterfalls. Their waters are supplied entirely by the rains and the melted snows of the high mountain peaks. The chief of these are the St Denis, Sêche, Est, Mat, and Remparts. Of these the Mat is the largest, and has a course of nearly 30 miles. Cultivation is confined almost entirely to those parts of the island that border on the sea-shore. The whole of the interior, except the Basin de Salazie in the Gros-Morne, is uninhabited. According to M. Bory, the island is divided into eleven parishes, St Denis, containing the capital of that name, which is the seat of government—Ste Marie, Ste Susanne, St André, St Benoit, St Rose, St Joseph, St Pierre de la rivière d'Abord, St Louis du Gaul, St Leu, and St Paul—and politically into two arrondissements, six cantons, and eleven communes. There is no good harbour in the island, and no safe anchorage off the coast. The effect of this disadvantage is to throw the trade into the hands of merchants from the Mauritius.

The climate of so mountainous a country as Bourbon is very va- Climate. rious, but on the whole healthy and pleasant, and by no means so hot as might be anticipated from its latitude. The hot season continues from the beginning of December to the end of March. The mean temperature throughout the year is 78° Fahrenheit. The inhabitants are healthy and long-lived, and the average annual mortality is only 1 in 42. They attribute their longevity in part to the periodical recurrence of tornadoes, which last for one or two

days, and have the effect of purifying and cooling the atmosphere.

Coffee, which was introduced from Mocha in 1717, was for a Produclong time the staple article of culture in Bourbon, and was reckoned tions. little inferior to that of Arabia. Cloves were also introduced and carefully cultivated, but never so as to compete successfully with those of the Eastern Archipelago. Cotton was formerly produced in large quantities, but in 1801 hurricanes and a disease which broke out among the trees discouraged the planters, who substituted coffee in its room. Of late years, the quantities of all these articles have greatly diminished, partly from local causes, and partly from

Bourbon-

Bourbon- the effects of competition upon the European markets. Since 1818, the cultivation of the sugar cane has almost entirely superseded that of coffee in the eastern and most fertile part of the island. The tobacco and cereals grown in the island do not supply the demand. Yams, potatoes, beans, and fruits, are found to thrive extremely well; and manioc, the food of the black population, grows in great abundance. Cattle are imported in considerable quantities from Madagascar, as the pasturage of Bourbon is insufficient to maintain the requisite number. The fisheries on the coast are valuable, and afford employment to nearly 500 persons. Coral and ambergris are found in considerable quantities off the shore. The manufactures of Bourbon are as yet in their infancy. The principal articles of manufacture are bricks, iron and tin goods. There are also several lime-kilns and tanneries, and one browery. The annual value of the articles thus manufactured is estimated at about L.50,000. In 1836 the amount and value of goods exported were-

Sugar	.18,173,092 k	ilog L.5	08,846
Coffee	. 990,013	.,	55,440
Cloves	. 566,650		56,140
Saltpetre			
Wood for cabinet work	112,811		1,519
Dye-woods	. 105,303		843

The total value of exports in this year was nearly L.670,000. The total value of imports, which, besides cattle and cereals, included oil, wine, timber, salt, &c., amounted to L.550,780. In 1852 the production of sugar amounted to 25,000,000 kilog., and was in the

Government, &c. fair way of doubling itself within two or three years. The chief magistrate of the island is the governor, who is sent out from the mother country. He is assisted by a council of thirty, elected from those French residents who pay L.8 and upwards of direct taxes. The electors in 1837 amounted to 1145, distributed into eight electoral colleges. They have also two representatives at Paris, with salaries of L 800 a-year each. Justice is administered by an imperial court, which sits at St Denis, two courts of assize, two tribunals of primary jurisdiction, one of which sits at St Paul, the other at St Denis, and by six justices of peace. In 1837 the troops of the line amounted to 814, the national guard to 6600. The revenue of the island in 1837 was L.85,982, the expenditure L.117,297, leaving a deficit of L.31,315. A college has been established in St Denis, and throughout the island there are 29 boys' schools and 24 girls' schools. The total number of pupils was, in 1837, 2316, of whom 1486 were boys and 830 girls. There are two hospitals, one at St Denis, and another at St Paul, in each of which towns there is also an establishment for the relicf of the poor; sixteen churches, two prisons, a chamber of commerce, a public library at St Denis, containing about 4000 volumes, and three private printing establishments. A bank was established in 1852. Four newspapers are printed on the island. In 1841 the population was 106,682, of whom 65,993 were free blacks. In 1850 it was 102,584.

BOURBON-LANCY, a small town of France, in the department of Soane-et-Loire, 27 miles W.N.W. of Charolles. It has numerous mineral springs, known to the Romans as the Aquæ Nisinei. Pop. 2848.

Bourbon-L'Archambault, a town of France, in the department of the Allier, 19 miles W. of Moulins. It was anciently the capital of the dukes of Bourbon, from whom the late royal family of France, and the existing sovereigns of Spain, Naples, and Lucca, are descended. It is now much frequented on account of its mineral waters, which are found to be peculiarly efficacious in nervous and rheumatic diseases. In 1789 it changed its name for that of Burges-les-Bains. It contains some remarkable specimens of Gothic and Byzantine architecture. Pop. 3017.

Bourbon-Vendée (now Napoléon-Vendée), a town of France, capital of the department of La Vendée, on the river Yon, in Lat. 46.41. N. Long. 1. 26. W. It was founded by Napoleon on the site of the ancient La Rochesur-Yon, and was called Napoléon-Vendée, in honour of its founder. At the Restoration its name was changed; but on the accession of Napoleon III. it resumed its original designation. Having neither trade nor manufactures, and situated in the midst of a heathy waste, it is regarded as the dullest town in France. The public buildings, erected by command of Napoleon, were so hastily built that they have already begun to fall into ruins. Pop. (1851) 6186.

BOURBONNAIS, an ancient province in the centre of France, embracing the present department of the Allier, and a portion of that of Cher. In 1527 it was forfeited to Bourbonneles-Bains the French crown. 11

Bour-

daloue.

BOURBONNE-LES-BAINS, a town of France, in the department of Haute Marne, in the arrondissement of Langres, and 21 miles E.N.E. of that town. It is much frequented on account of its hot saline springs, which are found on the site of the old Roman baths. The heat of these springs varies from 120° to 156° Fahrenheit. The number of visitors is about 800 annually. Pop. 3683.

BOURCHIER, John, Lord Berners, grandson and heir of a lord of the same name, who was descended from Thomas of Woodstock, Duke of Gloucester, and had been knight of the Garter and constable of Windsor Castle. Bourchier was created a knight of the Bath on the marriage of the Duke of York, second son of Edward IV., and was first known by quelling an insurrection in Cornwall and Devonshire, raised by Michael Joseph, a blacksmith, in 1495, which service recommended him to the favour of Henry VII. He was a captain of the pioneers at the siege of Theroanne under Henry VIII., by whom he was made chancellor of the exchequer for life, and lieutenant of Calais and the Marches; appointed to conduct the Lady Mary, the king's sister, into France on her marriage with Louis XII.; and had the extraordinary fortune of continuing in favour with Henry VIII. for the space of eighteen years. He died at Calais in 1532, aged 65. By King Henry's command he translated Froissart's Chronicle, which was printed in 1523, by Pynson, the scholar of Caxton. His other works were a whimsical medley of translations from French, Spanish, and Italian novels. These were, the History of the most Noble Valyaunt Knyght, Arthur of Lytell Brytayne; the Famous Exploits of Sir Hugh of Bourdeaux; the Golden Boke of Marcus Aurelius; and the Castle of Lone. He composed also a book on the duties of the inhabitants of Calais; and a comedy entitled Ite in Vineam, which was acted at Calais after vespers.

BOURDALOUE, Louis, a celebrated preacher, and one of the greatest orators that France has ever produced, was born at Bourges, August 20. 1632. At the age of sixteen he entered the Society of Jesus, of which he was destined to become one of the greatest ornaments, and there completed his studies. His able masters, who early discerned his talents, successively confided to him the chairs of humanity, of rhetoric, of philosophy, and of moral theology; and it was only after passing through these different probationary employments that he arrived at the eminent post which was designed for him, and was deemed qualified for mounting the pulpit.

In order to form an idea of the difficulties which he had to surmount, and of the talents which he displayed, it is only necessary, on the one hand, to call to mind the ridiculous manner and inflated style of the preachers of that period; and, on the other, to figure the young Jesuit at issue with the bad taste as well as the bad habits of the time; combating at once the passions, the vices, the weaknesses, and the errors of humanity, and overcoming his enemies, sometimes with the arms of faith, and sometimes with those of reason.

At first he preached for some time in the province, but his superiors afterwards called him to Paris. This took place in 1669, at the most brilliant epoch of the age of Louis XIV. when nothing was talked of but the victories of Turenne, the festivities of Versailles, the masterpieces of Corneille and Racine, the encouragement afforded to the arts, and the general impulse given to the human mind. Bourdaloue suddenly appeared in the midst of these fascinations, and, far from diminishing their effects, the severity of his ministry, and the gravity of his eloquence, served rather to enhance their splendour. His first sermons met with prodigious success, and all voices were raised in loud applause of the preacher. Madame de Sevigné, sharing the universal enthusiasm, wrote to her daughter that "she had never

Bourg.

Bourdaloue. heard anything more beautiful, more noble, more astonishing, than the sermons of Father Bourdaloue." Louis XIV. also wished to hear him, and the new preacher was in consequence sent to court, where he preached the Advent in 1670, and the Lent in 1672; and he was afterwards called for the Lents of 1674, 1675, 1680, and 1682, and for the Advents of 1684, 1689, and 1693. This was a thing unheard of before, the same preacher being rarely called three times to court. Bourdaloue, however, appeared there ten times, and was always received with the same ardour. Louis XIV. said that "he loved better to hear the repetitions of Bourdaloue than the novelties of any one else." After the revocation of the edict of Nantes, he was sent to Languedoc to preach to the Protestants, and confirm the newly-converted in the Catholic faith; and in this delicate mission he managed to reconcile the interests of his ministry with the sacred rights of humanity. He preached at Montpellier in 1686 with prodigious success, Catholics and Protestants being all equally eager to recognise in this eloquent missionary the apostle of truth and of virtue.

In the last years of his life Bourdaloue abandoned the pulpit, and devoted himself to charitable assemblies, hospitals, and prisons, where his pathetic discourses and insinuating manners never failed of their effect. He had the art of adapting his style and his reasonings to the condition and the understanding of those to whom he addressed either counsel or consolation. Simple with the simple, erudite with the learned, and a dialectician with sophists and disputants, he came off with honour in all the contests in which zeal for religion, the duties of his station, and love of mankind, led him to engage. Equally relished by the great and by the commonalty, by men of piety and by people of the world, he exercised till his death a sort of empire over all minds; and this ascendancy he owed as much to the gentleness of his manners as to the force of his reasonings. "His conduct," says one of his contemporaries, "is the best answer that can be made to the Lettres Provinciales." No consideration was ever capable of altering his frankness or cor-

rupting his probity.

Boileau, who detested the Jesuits, loved and often visited Bourdaloue. He may with justice be regarded as the reformer of the pulpit and the founder of Christian eloquence among the French. That which distinguishes him from other preachers is the force of his reasoning, and the solidity of his proofs. Never did Christian orator infuse into his discourses more majesty, dignity, energy, and grandeur. Like Corneille, he has been charged with overlabouring his diction, and accumulating idea upon idea with a needless superfluity of illustration—of speaking more to the understandings than to the hearts of his auditors, and sometimes enervating his eloquence with too frequent a use of divisions and subdivisions. But even in subscribing to these criticisms, which are to a certain extent well founded, it is impossible not to admire the inexhaustible fecundity of his plans—the happy talent velut imperatoria virtus, which he possessed, of disposing his reasonings in the order best calculated to command victory—the exact, constrictive logic with which he excludes sophisms, contradictions, and paradoxes-the art with which he lays the foundations of our duty in our interest-and, finally, the inestimable secret of converting the details of manners and habits into so many proofs of his subject. Parallels have often been drawn between Bourdaloue and Massillon; but the talents of these great pulpit orators lay in different directions, and they may therefore be more fitly contrasted than compared. If Massillon is now read with a more lively interest, he owes this advantage to the charms of his style rather than to the force of his reasonings. Among the critics of the present day, the preference is unhesitatingly given to the rival of Racine, to the painter of the heart, to the author of the discourse on the small number of the elect; but if we consult the

contemporaries of Massillon himself, we shall find that they Bourdelot assign him only the second rank. According to them, Bourdaloue preached to the men of a vigorous and masculine age; Massillon to those of a period remarkable for its effeminacy. Bourdaloue raised himself to the level of the great truths of religion; Massillon conformed himself to the weakness of the men with whom he lived. The bishop of Clermont will always be read; but if the simple Jesuit could raise his commanding voice from the tomb, and again roll forth a majestic stream of divine truth, the courtly accents of his rival would no longer be heard, and the charms of his diction would be forgotten. The first part of his celebrated Passion, in which he proves that the death of the Son of God is the triumph of his power, has generally been considered as the great masterpiece of Christian eloquence. Bossuet has said nothing stronger or more elevated. The second part, however, is inferior to the first, though considered by itself, alike beautiful and convincing.

The discourses of Bourdaloue have been described by a celebrated French critic as embodying in them a complete course of theology. This is perhaps going a little too far; but still their general merit is very great, and for nothing are they more distinguished than their comprehensiveness. The diction of this great preacher is always natural, clear, and correct; sometimes deficient in animation, but without vacuity or languor, and generally relieved by outbreakings

of much force and originality.

Two editions of Bourdaloue's works were published at Paris by Père Bretonneau, a Jesuit; one in 16 vols. 8vo, 1707-34, and the other, from which the editions of Rouen, Toulouse, and Amsterdam were afterwards printed, in 18 vols. 12mo, 1709-34. The works are distributed as follows, viz., 1. Deux Avents, prêché devant le Roi, 1 vol.; 2. Carème, 3 vols. 8vo, or 4 vols. 12mo; 3. Mystères, 2 vols.; 4. Fêtes des Saints, Vetures, Professiones, Oraisons Funèbres, 2 vols.; 5. Dominicales, 3 vols.; 6. Exhortations et Instructions Chrétiennes, 2 vols.; 7. Rétraité Spirituelle, 1 vol.; 8. Pensées, in 2 and in 3 vols. The Versailles edition appeared in 1812-13, in 16 vols. 8vo. It is much inferior to the former. Of recent editions, the best are those of 1822-26, 17 vols. 8vo, of 1833-34, and of 1840, 3 tom, gr. 8vo. The Sermons Inédites de Bourdaloue, published by the Abbé Sicard in 1810, are apocryphal. (Vie de P. Bourdaloue, par Madame de Prigny; Esprit de Bourdaloue, par l'Abbé de la Porte; and Biographie Universelle). (J. B—E.)

BOURDELOT, JEAN, a learned French critic, who distinguished himself by annotations on Lucian, Petronius, and Heliodorus; a Universal History; Commentaries on Juvenal; a Treatise on the Etymology of French words; and several other works which were never published. He died in 1638.

His nephew, the Abbé Bourdelot, changed his name from Pierre Michon to oblige his uncle. He was a celebrated physician in Paris; was much patronized by Christina of Sweden; and gained great reputation by a Treatise on the

Viper, and other works. He died in 1685.

BOURDON, SÉBASTIEN, an eminent painter, born at Montpellier in 1616. He spent seven years in Italy, where he formed an acquaintance with Andrea Sacchi and Claude Lorraine, and acquired so great a reputation, that, on his return to France, he was appointed rector of the academy of painting in Paris, being the first who held that office. He succeeded better in landscapes than in history. His pieces are seldom finished, and those which received his last touches are not always the finest. His chef d'œuvre is the Martyrdom of St Peter in the cathedral of Notre Dame at Paris. His talents as an engraver also were considerable. Bourdon was a Calvinist, and lived much respected, even in a Catholic country, his life and manners being unexceptionable. He died in 1671.

BOURG, or Bourg-en-Bresse, a very ancient town of France (supposed by De Thou to be the Forum Segusianorum of the Romans), capital of the department of Ain, on the Revssouse, in Lat. 46. 12. N. Long. 5. 13. E. It belonged at one time to the dukes of Savoy, but was taken

Bourgelat by the French in 1536, and in 1600 formally ceded to France by the treaty of Lyons. It was an episcopal town Bourgoing from 1515 to 1536. It possesses a civil court of primary jurisdiction, a communal college, and a public library of 19,000 volumes. Several important grain-markets are held in the town, which is in the midst of an agricultural district. There is also a considerable trade in wines, skins, poultry, horses, and cattle. The chief manufactures are linen, cotton, hosiery, and basket-work. In the neighbour-hood is the church of Notre Dame de Brou, built in 1511 by order of Margaret of Austria, aunt of Charles V., and considered one of the finest architectural monuments of that age. Vaugelas the grammarian, and Lalande the astronomer,

were born here. Pop. (1851) 9698.

BOURGELAT, CLAUDE, who may be called the father of veterinary science, was born at Lyons in 1712, and died in 1799. He entered the law, but abandoned that profession in disgust at having gained an unjust suit for a client. Embracing the military profession, he served in the cavalry, and thus had ample opportunity of studying the diseases of animals. In 1772 he opened at Lyons a veterinary school, which soon became celebrated over Europe. His great success induced the government to establish several similar institutions; and Bourgelat was appointed to superintend the school established at Alfort, which became, and continues to be, the chief seat of veterinary science in France. Bourgelat was a member of the Academy of Sciences of Paris and of Berlin, and corresponded with some of the most eminent men of science of his time. His works on veterinary subjects are numerous and valuable.

BOURGES, a town of France, capital of the department of Cher, is situated at the confluence of the Auron and Evre, in Lat. 47. 6. N. Long. 2. 25. E., 100 miles S. of Paris. It is the Avaricum of Cæsar, by whom it was burnt down B.C. 52. Under Augustus it became the capital of Aguitania, which it continued to be for nearly 500 years. After this it was more than once destroyed, but was always rebuilt; and under Philip Augustus it became the capital of Berri. Bourges has been long celebrated for its cathedral, which is reckoned one of the finest in France. It is the see of an archbishop, and possesses a royal college, a diocesan seminary, and a public library of 25,000 volumes, with some rare manuscripts. The principal manufactures are cutlery, and linen and woollen goods. There are also several breweries and tan-works. The trade is confined to corn, wool, hemp, hides. The nurseries in the neighbourhood are famous. Louis XI. was a native of Bourges, and, in compliment to his birth-place, founded a university there, long celebrated; which, however, was suppressed at the Revolution. Cujas the famous jurist was one of the professors. Louis likewise gave patents of nobility to the mayor and magistrates of the town. Bourdaloue, the pulpitorator, was a native of Bourges, as was also Jacques Cœur, the unfortunate minister of Charles VII. Pop. in 1851, 22,465.

BOURGET, JEAN, a learned French antiquary, born near Falaise in 1724. He was educated at Caen, and in 1745 he became a Benedictine monk of the abbey of St Martin de Seèz. His merit and learning procured his translation to the abbey of Bec, where he resided till 1764. He was elected an honorary member of the Society of Antiquaries of London in 1765; and the same year returned to the abbey of St Stephen at Caen, where he continued till his death in 1775. He left behind him, in manuscript, large and accurate accounts of some of the principal Norman abbeys. The History of the Royal Abbey of Bec, which he presented to Dr Ducarel in 1764, is only an abstract of his larger work.

BOURGOING, JEAN FRANÇOIS, a distinguished French diplomatist, was born at Nevers in 1748, and died at Carlsbad in 1811. Most of his life was spent in the discharge

of various diplomatic offices, at the courts of Spain, Denmark, Sweden, and Saxony. His principal work is his Tableau guignons de l'Espagne Moderne (1789, 3 vols. 8vo), which has been Bouterwek translated into English, German, and Danish.

BOURGUIGNONS, or Burgundians. See Bur-

GUNDIONES.

BOURIGNON, ANTOINETTE, a noted Flemish fanatic, born at Lisle in 1616. Setting up as a reformer, she maintained that reason and common sense ought to give place to the illumination of divine faith. Of her pretended visions and revelations many absurdities have been published. Her manners and appearance were repulsive, her temper was morose and peevish, her cupidity excessive, and her character as a woman questionable. Dressed like a hermit, she travelled through France, Holland, England, and Scotland, and made some thousand converts, known by the name of Bourignonists. Her works were published in 1686 at Amsterdam, in 21 vols. 8vo. One of these, entitled The Light of the World, was published in English in 1696; and her tenets were for a while popular in Scotland. Their aim was to guide her followers to an imaginary perfection, and to make them renounce all forms in favour of an interior and mystic worship. Though she inherited a considerable fortune, she never gave anything to the poor, on the pretence that they might make a bad use of her liberality Yet at her death, which took place at Francker in 1680, she left all her property to a hospital.

BOURNE, a market-town of England, in the county of Lincoln and wapentake of Aveland, 97 miles from London. It has four principal streets diverging from the market-place, in the centre of which is the new town-hall, erected in 1822. The church is a fine old Gothic edifice: of its two towers only one is now standing. It has an endowed grammar-school, national school, mechanics' library, hospital, almshouse, and a union poor-house. Pop. (1851) 2789, principally engaged in the leather, wool, and malt trade. Market-day Saturday. A tesselated pavement and some Roman coins have been found in the neighbourhood. Cecil, Lord Burleigh, was born here in 1520, and the un-

fortunate Dr Dodd in 1729.

BOURNONITE, a mineral consisting of sulphuret of lead, antimony, and copper, first found in Cornwall, and

afterwards in Hanover, Mexico, and Peru.

BOURRIENNE, FAUVELET DE, the early friend and the biographer of Napoleon, was born at Sens in 1769, and died at Caen in a lunatic asylum in 1834. He accompanied Bonaparte to Egypt as his secretary, and continued in that situation under the consulship; went in 1804 as ambassador to Hamburg; and after the fall of his old master, held office under Louis XVIII. The revolution of 1830, and the loss of his fortune, unhinged his reason. His Mémoires, in 10 vols. 8vo, 1829-31, contain much interesting information regarding Napoleon. Their defects were exposed in a work, entitled Bourrienne et ses erreurs volontaires et involontaires, Paris, 1830, 2 vols. 8vo.

BOUSSA, a large town of Central Africa, capital of a province of the same name, in the kingdom of Borgoo. It is situated on an island of the Niger, in Lat. 10. 14. N. Long. 5. 20. E., and is a place of considerable strength, being inclosed by a well-built wall. Pop. variously estimated from 10,000 to 18,000. It was here that the enterprising traveller Park met his untimely death.

BOUSTROPHEDON (from β oûs, and $\sigma\tau\rho$ o ϕ $\dot{\eta}$), a term descriptive of the early Greek manner of writing, in which the lines ran from left to right and from right to left alternately. It was so named from its resemblance to the path of oxen in ploughing a field. In this manner Solon's laws were written, and also the Sigeian Inscription, ap. Böckh

BOUTERWEK, FRIEDRICH, a German author, chiefly distinguished for his elaborate work on modern literature.

Bowles.

Bouts-Rimés Bow.

entitled Geschichte der Neuern Poesie und Beredsamheit, in 12 vols. 8vo, 1801-19. He was born at Ocken, near Goslar, in 1766, filled the chair of mental philosophy at Göttingen from 1797, and died at Göttingen in 1828. In philosophy he at first adopted the system of Kant, but afterwards forsook it for that of Jacobi. His great work has been translated into various languages. It bears the stamp of a refined taste, and an intimate acquaintance with the literature of Europe. The volume on Spanish literature, and Ticknor's later work, are the best on the subject.

BOUTS-RIMES, in French poetry, a set of rhymes, disposed in order, and given together with a subject, to be filled up with verses. The invention is ascribed to one Ducot, in the year 1649. In fixing the bouts, it was usual to choose such as seemed to have the least connection. The academy of Lanternists at Toulouse contributed towards keeping in countenance the bouts-rimés, by proposing annually a set of fourteen, to be filled up on the glories of the Grand Monarque, and by offering a medal as the prize. The following, filled up by Commire, is a specimen of these conceits:-

> Tout est grand dans le roi, l'aspect seul de son buste Rend nos fiers ennemis plus froids que des Et Guillaume n'attend que le tems des Pour se voir succomber sous un bras si Qu'on ne nous vante plus les miracles d' Louis de lien regner lui feroit des Horace en vain l'égale aux dieux dans ses Moins que mon héros il étoit sage et

glaçons; moissons, robuste. Auguste. leçons; chansons; juste.

BOVINO (the ancient Vibinum), a fortified town of Naples, province of Capitanata, 18 miles S.S.W. of Foggia. It is the seat of a bishopric, of a court of primary jurisdiction, and has a cathedral, and several churches and convents. Pop. 5200. Here the Imperialists defeated the Spaniards in 1734.

BOW (arcus), a weapon of offence, made of wood, or other elastic matter, which, being strongly bent by means of a string fastened to its two ends, throws an arrow with great force in suddenly recovering its natural state. It is also called the long-bow, by way of distinction from the cross-bow or arbalest.

The bow is the most ancient and the most universal of all weapons, and is found amongst the most barbarous and remote tribes in every part of the world.

The use of the bow was first abolished in France under Louis XI., and in its place were introduced the halberd, pike, and broadsword. The long-bow was formerly greatly used in England: most of our victories in France were acquired by it, and many laws were made to regulate and encourage its use. See Archery.

The Laplanders construct their bow of two pieces of tough wood of the same size, and flattened on each side, the two pieces being united very firmly together by means of a strong glue. A bow thus constructed possesses a much greater propulsive power than another of the same dimensions formed of a single piece.

Among the ancients, the bow-string was of horse hair; though Homer's bow-strings were frequently made of hide cut into small thongs. The tip of the bow, to which the string was fastened, was called κορώνη, and was frequently made of gold. The Grecian bows were frequently beautified with gold or silver; whence the epithet of 'Αργυρότοξος bestowed on Apollo. But the matter of which they were ordinarily composed seems to have been wood, although they were anciently, Scythian-like, made of horn, as appears from the description of the bow of Pandarus in Homer.

The invention of the bow is usually ascribed to Apollo, and it was communicated to the primitive inhabitants of Crete, who are said to have been the first of mortals that understood the use of bows and arrows. Accordingly, even in later ages, the Cretan bows were famous, and preferred

by the Greeks to all others. The Scythians and the Parthians were especially celebrated for their skill in archery.

The Scythian bow was distinguished from the bows of Greece and other nations by its incurvation, which was so great as to form a half moon or semicircle; and hence the shepherd in Athenæus, describing the letters in Theseus's name, and expressing each of them by some apposite resemblance, compares the third to the Scythian bow, meaning not the more modern character 2, but the ancient C, which is semicircular, and bears the third place in the name of the hero, @HCEVC, as spelt in ancient Greek.

Cross-Bow (also called arbalest or arbalet, from arbalista, or rather arcubalista, "a bow with a sling"), a steel bow set in a shaft of wood, furnished with a string and a trigger. It is bent with a piece of iron fitted for that purpose, and serves to project bullets, darts, and other missiles. See also Ballista.

Bow, in Ship-Building. See Ship-Building.

Bow-Net, an instrument for catching fish, chiefly lobsters. It consists of two round wicker baskets, pointed at the end, one of which is thrust into the other; and at the mouth there is a little rim, four or five inches broad, bent somewhat inwards.

BOWDICH, THOMAS EDWARD, born at Bristol in 1790, was brought up by his father to mercantile affairs. and in 1814 obtained an appointment on the western coast of Africa. Two years afterwards, on his return home, he was sent out by the African Company as their agent to the king of the Ashantees. In 1819 he published a quarto volume giving an account of that remarkable people. He then seems to have spent a considerable time at Paris in the study of the natural sciences. During his stay in Europe he edited several works on Africa, and published an excellent pamphlet on the British settlements on the western coast of Africa. In 1822 he set out for Africa once more, with a firm resolution of devoting himself to the exploration of its interior; but he was attacked with the country fever on the Gambia, and died January 10th 1824. His widow, who had accompanied him, edited several posthumous productions of his pen.

BOWDITCH, NATHANIEL, a self-taught American mathematician, born in 1773, of humble parents, at Salem in Massachusetts. He was bred to his father's business as a cooper, and afterwards was apprenticed to a ship-chandler. His taste for mathematics early developed itself; and he acquired Latin that he might study Newton's Principia. In 1795 he sailed as supercargo, in which capacity he made four long voyages; and, being an excellent navigator, he afterwards commanded a vessel, instructing his crews in taking lunar and other observations. He edited three editions of Hamilton Moore's Navigation. In 1804 he became actuary to a Boston insurance company; and in the midst of his active and useful career published a translation of the Mécanique Celeste of Laplace, with annotations ;—a work which will better prove the great acquirements of this selftaught philosopher than any laboured panegyric. He died in 1838, at Boston.

BOWER (Saxon bur, a chamber, a hut), a place under covert of trees, differing only from an arbour in being round or square, with a kind of dome or ceiling at top, whereas the arbour is properly long and arched.

Bower Anchor. See Anchor.

BOWIE-KNIFE, the name given to a large clasp-knife used by hunters and others in America, especially in the western States.

BOWLES, REV. WILLIAM LISLE, author of sonnets and other poems, was born at King's Sutton in Northamptonshire in 1762. He was educated at Winchester and at Trinity College, Oxford; and, having entered into holy orders, he received various preferments in the church. He is represented as having been an accomplished perBowline Bowyer.

son, and possessed of an agreeable and playful disposition. By an edition which he published of the works of Pope he became involved in a controversy with Lord Byron; to which circumstance he was perhaps not a little indebted for the reputation he enjoyed. He died in 1850.

BOWLINE, a rope leading forward from the leech (side border) of a square sail, to keep it tightly out. When a vessel is sailing close-hauled she is then said to be sailing on a bowline or on a taut bowline. Bowline bridles are the spans of cord by which the bowline is fastened to the leech.

BOWLING, a game played in the open air with wooden bowls (generally made of lignum vitæ) on a smooth greensward or in a close bowling alley. A small ball, called a block or jack, is rolled to a convenient distance, and forms the mark towards which the player aims. Each player is provided with two bowls, and the party who counts the greatest number of best bowls, i.e., nearest the block, wins the game, which is usually thirteen casts or best bowls. Four or five persons to a side is the largest number that can conveniently join in the game. The bowl is constructed with a bias to one side, so that its direction towards the mark forms a gentle curve. When a bowl strikes the jack and removes it from its original position, the aspect of the game is generally altered, the relation of the bowls to the mark at the final throw being that which decides their respective value.

Bowling-Green, a level piece of ground kept smooth for bowling. In Gardening it signifies a parterre in a grove, laid with fine turf, smoothly shaven, and laid out in compartments of divers figures, with dwarf trees and other decorations. Bowling-greens are of English origin, but have been adopted by the French and Italians for ornament.

BOWSPRIT, or BOLTSPRIT, a large spar which projects over the stem of a ship, resting slopewise on the head of the main stem, and having its lower end fastened to the partners of the fore-mast, and further supported by the forestay. It carries the sprit-sail, sprit-top-sail, and jack-staff; and its length is usually the same as that of the fore-mast.

BOWYER, an artificer whose business is to make bows; in which sense bowyers were distinguished from fletchers, who made arrows.

Bowyer, William, the most learned printer of his age, was born at Whitefriars, London, in December 1699. His father, whose name was also William, had been eminent in the same profession; and his maternal grandfather, Icabod Dawks, was employed in printing the celebrated Polyglot Bible of Bishop Walton. He received his early education under Mr Ambrose Bonwicke, a nonjuring clergyman at Headly, near Leatherhead, in Surrey; and in 1716 was admitted a sizar at St John's College, Cambridge. After leaving the university he entered into business with his father, who was an eminent printer. The attainments which Bowyer brought into the printing office had long been unusual in such establishments; and he was thus enabled to issue many important works in a style that elicited universal commendation, and placed his name in the foremost ranks

One of his most valuable contributions to literature was an excellent edition of the Greek Testament, published in 1763, in 2 vols. 12mo, entitled Novum Testamentum Græcum; ad fidem Græcorum solum Codicum MSS. nunc primum impressum, adstipulante Joanne Jacobo Wetstenio, juxta Sectiones Jo. Alberti Bengelii divisum; et nova interpretatione sæpius illustratum : Accessere in altero volumine, Emendationes Conjecturales virorum doctorum undecunque collectæ. New editions of these conjectural emendations appeared in 1772, 1782, and 1812.

In 1774 he corrected a new edition of Schrevelius's Greek Lexicon; to which he added a number of words, which he himself had collected in the course of his studies. Considerable manuscript additions were also made by him to the lexicons of Hederic and Buxtorf, the Latin ones of Faber and Littleton, and the English dictionary of Bailey; and he left behind him many other proofs of his critical skill Box-Wood, in the learned languages. In 1774 was published The Origin of Printing, in two Essays. The original idea of this valuable tract was Bowyer's, but it was completed by Nichols.

His death took place in November 1777, when he had nearly completed his seventy-eighth year. For more than half a century he was unrivalled as a learned printer, and many of the most masterly productions of this kingdom issued from his press. To his literary and professional abilities he added an excellent moral character, inflexible probity, and an uncommon alacrity in relieving the necessitous. (Nichols' Anecdotes Literary and Biographical of William

BOX, a chest or coffer, of wood or metal, &c.

 D_{ICE} -Box, a channelled cylindrical box used in gaming for shaking and throwing the dice. It answers to the Roman fritillus.

BOX-HAUL, in Navigation, to bring a ship, when close hauled, round upon the other tack, when she refuses to stay and there is not room to wear.

BOXHORN, MARK ZUER, a learned Dutch critic, was born at Bergen-op-Zoom in 1612. Before he was of age he was appointed to the chair of eloquence at Leyden, having already published editions of the Scriptores historia Augustæ, the Poetæ Satyrici Minores, and some other Latin works. He refused the invitations of Queen Christina to remove to Sweden; and on the death of the learned Daniel Heinsius succeeded him as professor of jurisprudence and history. He died in 1653, from the effects, it is said, of immoderate indulgence in tobacco. His principal works are Poemata, 1629, 12mo; Theatrum, seu Comitatus Hollandiæ nova descriptio, Amst. 1632, 4to; Originum Gallicarum liber, Amst. 1654, 4to, &c.

BOXING, called pugilatus by the Romans, the exercise of fighting with the fists, either naked or with a stone or leaden ball grasped in them. In the pugna cæstuum the combatants had leathern thongs on their hands, which in later times were loaded with lead or iron, to add greater force to the blows. Three species of boxing may be distinguished, namely, where both the head and hands were naked; where the hands were armed and the head naked; and where the ears were defended with a kind of covers, called amphotides, and the hands also furnished with the cæstus.

The ancient pugilists battled with extraordinary fury, and frequently received such disfigurements that they could not be recognised by their acquaintances. They were thus rendered the subject of many railleries, of which some humorous specimens are to be found in the Greek Anthology.

Boxing was practised in the heroic ages; and hence even gods, as well as several of the earliest heroes, are represented as distinguished pugilists; as, for example, Apollo, Hercules, Tydeus, &c. The invention of the art, says the scholiast on Pindar (Nem. v. 89) was ascribed to Theseus.

Boxing the Compass, denotes the rehearing the points in their proper order.

BOXING also signifies the tapping of a tree, to make it

yield its juice.

BOX-WOOD, the wood of Buxus sempervirens, a native of most parts of Europe. The tree grows well in England, as at Boxhill, &c., but that from the Levant is most esteemed. Turkey box is yielded by Buxus balearica, a species which is found in Minorca, Sardinia, and Corsica, as well as in European and Asiatic Turkey. This is the most valuable kind, selling in the English market at from L.4, 10s. to L.8, 15s. a ton. Box is also found on Mount Caucasus, and a species extends even to the Himalaya mountains. It is called shumshad by the Arabs. Boxwood is of a yellowish

Boyaca || Boyce. colour, very hard, close-grained, and durable, and susceptible of a high polish. It is greatly used by the wood-engraver, the turner, carver, mathematical-instrument and flute maker, &c. This tree was much cultivated by the Romans, as described by Pliny; and it appears also to have been the *teashur* mentioned in Scripture as one of the woods used in adorning the temple of Solomon. The specific gravity of Dutch boxwood is given by Muschenbroek as 1.3280.

BOYACA, one of the seven departments into which the republic of New Grenada is divided, comprises the four provinces of Pamplona, Casanare, Tunja, and Socorro. Pop. about 600,000. The capital is Tunja. The town of Boyaca is five miles south of Tunja, and is celebrated for the victory gained by Bolivar over the Spaniards on 7th August 1819.

BOYAR, or Boiar, a title of nobility in the Russian em-

pire, corresponding to the English baron.

BOYAU, in Fortification, a ditch covered with a parapet, which serves as a communication between two princi-

pal trenches.

BOY-BISHOP. From a remote period, in the cathedrals and greater churches of Christendom, it was the custom on St Nicholas day (Dec. 6) to select a child, usually one of the choir, and to invest him with the robes and other insignia of the episcopal office; and from the time of his election until the feast of the Holy Innocents (Dec. 28), the boy-bishop continued to practise a kind of mimicry of the ceremonies of the church, for the amusement of the people. This custom, which was countenanced by the great ecclesiastics themselves, continued to exist till the year 1542, when it was finally suppressed by royal proclamation. (See Ellis's edition of Brand's *Popular Antiquities*, vol. i.)

BOYCE, HECTOR, a distinguished historian, was born at Dundee about the year 1465, being descended of a family which for several generations had possessed the barony of Panbride or Balbride. The orthography of his surname is extremely fluctuating: it is to be found under the various modifications of Boece, Boeth, Boeis, Boys, Boyse, Boyes, Boyis, Boiss, and Boyce. The first of these, we strongly suspect, was never a name belonging to any living man in Scotland: it was formed by the French from the name of the latest Roman classic, and on that account appears to have been adopted by Bellenden in his translation of the history. The real Scottish name is a monosyllable; and we adhere to the orthography of Boyce, as being most common in our own time. He received the first rudiments of learning at Dundee, and completed his course of study in the university of Paris, where he took the degree of B.D. He was appointed a professor of philosophy in the College of Montaigu; and in this seminary he became intimately acquainted with Erasmus, who in two epistles has testified his esteem for Boyce's character.1 In his academical station he had already distinguished himself by his talents and attainments, when King's College was founded at Aberdeen by the munificence of William Elphinstone, bishop of the diocese. The papal bull for the erection of a university had been obtained in the year 1494, but the buildings were not sufficiently advanced, nor did the lectures commence, till about the year 1500. It was not without some degree of hesitation that he consented to

quit the lettered society of Paris, and to become principal of this new college; but having at length accepted the conditions, he proceeded to Aberdeen, and experienced a kind reception from the canons of the cathedral, several of whom he has commemorated as men of learning. It was a part of his duty as principal to read lectures on divinity. The sub-principal was his friend William Hay, a native of the same county, who had been his fellow-student at Dundee and at Paris, and who at length succeeded him as head of the college.2 The principal's brother, Arthur Boyce, doctor of the canon and licentiate of the civil law, was appointed professor of the canon law, and afterwards became a judge of the court of session.3 The common branches of science and literature were taught with zeal and success; and the prosperity of the institution was greatly promoted by the talents and by the reputation of Boyce.

The emoluments of his office were not such as appear very dazzling to modern eyes. "Boethius, as president of the university," says Dr Johnson, "enjoyed a revenue of forty Scottish marks, about two pounds four shillings and sixpence of sterling money. In the present age of trade and taxes, it is difficult even for the imagination so to raise the value of money, or so to diminish the demands of life, as to suppose four and forty shillings a-year an honourable stipend; yet it was probably equal not only to the needs but to the rank of Boethius. The wealth of England was undoubtedly to that of Scotland more than five to one, and it is known that Henry the Eighth, among whose faults avarice was never reckoned, granted to Roger Ascham, as a reward of his learning, a pension of ten pounds a year." But it is necessary to recollect that this was not the only preferment which Boyce enjoyed: he was not only principal of King's College, but was likewise a canon of Aberdeen, and rector of Tyrie in the same Under the date of July 14. 1527, we find a "grant to Maister Hector" of an annual pension of fifty pounds, to be paid by the sheriff of Aberdeen out of the king's casualties: and on the 26th of July 1529 was issued a "precept for a lettre to Mr Hector Boys, professor of theology, of a pension of L.50 Scots yearly, until the king promote him to a benefice of 100 marks Scots of yearly value; the said pension to be paid him by the customers of Aberdeen." In 1533 and 1534, one-half of his pension was, however, paid by the king's treasurer, and the other half by the comptroller; and as no payment subsequent to that of Whitsuntide 1534 has been traced in the treasurer's accompts, he is supposed to have obtained his benefice soon after that period.

His earliest publication, the lives of the bishops of Aberdeen, appeared under the subsequent title: "Episcoporum Murthlacensium et Aberdonensium per Hectorem Boetium Vitæ." Impressa sunt hæc prelo Ascensiano, ad Idus Maias anno Salutis M.D.XXII., 4to. This little volume, which is of great rarity, has been reprinted for the members of the Bannatyne Club—"Hectoris Boetii Murthlacensium et Aberdonensium Episcoporum Vitæ, iterum in lucem editæ." Edinb. 1825, 4to. Of the bishops of this diocese the seat was originally at Murthlack, in the county of Banff, but it was afterwards transferred to Aberdeen. His notices of the early prelates are necessarily brief and unsa-

2 In Orem's Description of King's College, Aberdeen, p. 154-7, he is erroneously called William Gray.

3 Boyce has mentioned his brother in very favourable terms: "Arthurus Boetius mihi germanus, in pontificio jure doctor, in civico (ut dicunt) licentiatus, vir multæ doctrinæ, plus literarum indies consecuturus, quod studium ei permanet animo indefesso, nobiscum jura pie et scite profitetur. Est in eo vis et gravitas eloquendi, a vulgari genere plurimum abhorrens. (Aberdonensium Episcoporum Vitæ, p. 63, edit. Edinb. 1825, 4to.)

Maitland's Biographical Introduction to Bellenden, p. xxiii.

that which relates to his liberal patron Bishop Elphinstone; of whose private history and public services he has given a circumstantial detail, which occupies nearly one-third of the volume. Here we likewise find an account of the foundation and constitution of the college, together with some notices of its earliest members.

His more famous work, the history of Scotland, was published after an interval of five years: "Scotorum Historiæ a prima gentis origine cum aliarum et rerum et gentium illustratione non vulgari: præmissa epistola nuncupatoria, tabellisque amplissimis, et non pænitenda Isagoge, quæ ab hujus tergo explicabitur diffusius. Quæ omni impressa quidem sunt Iodoci Badii Ascensii typis et opera; impensis autem nobilis et prædocti viri Hectoris Boethii Deidonani, a quo sunt et condita et edita." Fol. The title and colophon have no date, but the commendatory epistle by Alexander Lyon, precentor of the cathedral of Elgin, bears the fifteenth of March 1527. This edition contains seventeen books. Another edition, containing the eighteenth book and a fragment of the nineteenth, was published by Ferrerius, who has added an appendix of thirty-five pages. Paris, 1574, fol. Though published at Paris, the latter edition appears from the colophon to have been printed at Lausanne.

The composition of Boyce's history displays much talent; and if the style does not always reach the standard of ancient purity, it displays a certain vein of elegance which generally renders it attractive. The author's love of his native country, and his anxiety to emblazon the heroic deeds of his countrymen, are conspicuous in every part of the work; nor must we leave unnoticed those aspirations after political freedom, by which he was honourably distinguished at a period when the human mind was so generally chained to the earth by the most slavish maxims of submission. It may be recorded as commendation, instead of reproach, that his principles of polity have been represented as no better than those of Buchanan. Boyce's imagination was, however, stronger than his judgment : of the extent of the historian's credulity, his narrative exhibits many unequivocal proofs; and if this circumstance admits of a sufficient excuse from the common propensity of the age in which he lived, his work presents strong indications of another fault, for which it is not so easy to find an apology. According to Bishop Lloyd, he put Fordun's tales "into the form of an history, and pieced them out with a very good invention, that part in which he chiefly excelled." He professes to

tisfactory, and the most interesting portion of the book is have obtained from the monastery of Icolmkill, through the Boyce. good offices of the Earl of Argyle and his brother the treasurer, certain original historians of Scotland, and among the rest Veremundus and Campbell, of whose writings not a single vestige is now to be found. In his dedication to the king, he is pleased to state that Veremundus, a Spaniard by birth, was archdeacon of St Andrews, and that he wrote in Latin a history of Scotland from the origin of the nation to the reign of Malcolm the Third, to whom he inscribed his work. According to Bishop Stillingfleet, whose opinion has been adopted by many other writers, these historians never existed except in Boyce's fertile imagination.3 From the charge of downright fabrication he has very recently been vindicated by Mr Maitland; but notwithstanding the ingenuity of the defence, we find it extremely difficult to divest ourselves of a strong impression, that the historian's account of his original materials, if not destitute of truth, is at least destitute of verisimilitude. His propensity to the marvellous4 was at an early period exposed in the following tetrastich of Leland, which Dempster has erroneously ascribed to Humphrey Lhuyd:5

> Hectoris historici tot quot mendacia scripsit, Si vis ut numerem, lector amice, tibi, Me jubeas etiam fluctus numerare marinos, Et liquidi stellas connumerare poli.6

Lhuyd, who attacked him in different works, spoke of his fabrications without management or scruple;7 nor did he experience much better treatment from Stanihurst, an Irish writer of considerable reputation.8 Of his merits as an historian, a very unfavourable estimate has more recently been formed by Lord Hailes and Mr Pinkerton. But in the opinion of Mr Wallace, a learned lawyer, his "elegant style and correct composition, not to add beautiful genius and fine fancy, are conclusive proofs that his understanding could not be inaccurate." And, as Mr Maitland has remarked, "in forming a final estimate of the literary character of Boece, we must bear in mind, that when scholar-craft in this country at least was rare, he was a scholar, and contributed, by reviving ancient learning, to dispel the gloom of the middle ages; and that, while the history of his country existed only in the rude page of the chroniclers who preceded him, or in the fading records of oral tradition, he embodied it in narrative so interesting, and language so beautiful, as to be worthy of a more refined age."10

Boyce's History of Scotland was translated into the Scottish language by John Bellenden, archdeacon of Moray and

¹ Joannes Ferrerius, a native of Picdmont, resided for several years in Scotland under the patronage of Robert Reid, abbot of Kinloss, and afterwards bishop of Orkney. In the dedication of one of his works to this prelate, he mentions Hector and Arthur Boyce, together with several other scholars of Aberdeen. "Aberdoniis rector a Kynkell, homo studiosus et politicus, me semper complexus est humanissime. Idem fecit Hector ille Boethius, historiarum vestrarum scriptor nunquam satis laudatus; ut interim omittam Arthurum Boethii fratrem germanum, utriusque juris peritissimum, Gulielmum Haye, theologum syncerum, ac Jacobum Vane, cum doctore medico peritissimo Roberto Gray. Adde his Joannem Vaus, virum cum literis tum moribus ornatissimum, et de juventute Scotica bene meri-(Auditum Visu præstare, contra vulgatum Aristotelis Placitum, academica Johannis Ferrerii Pedemontani Dissertatio. Paris, 1539, 4tc.) With respect to his literary character, see Lord Hailes's Examination of some of the Arguments for the high Antiquity of Regiam Majestatem, p. 20. Edinb. 1769, 4to. Among various other works, he wrote a history of the abbots of Kinloss, which is printed, though not without abbreviation, in Martene and Durand's Veterum Scriptorum et Monumentorum Collectio, tom. vi.

² Lloyd's Historical Account of Church Government in Great Britain and Ireland, pref. 3 Stillingfleet's Antiquities of the British Churches, p. 255.

⁴ One of the letters of Joseph Scaliger contains the subsequent passage relative to Boyce's story of the barnacles or soland-geese; "Nam de conchis anatiferis fabula prorsus est. Nullæ enim anates ex conchis producuntur, sed ex putredine vetustorum navigiorum, quibus conchæ adhærent, anates quasdam nasci certum est. Etiam arbores anatiferas esse in ultima Scotia, ubi nullæ prorsus arbores sunt, hactenus mentita est scriptorum vernilitas." (Scaligeri Epistolæ, p. 729. Lugd. Bat. 1627, 8vo.) See likewise Nicolai Nancelii Analogia Microcosmi ad Macrocosmon, col. 835. Lutetiæ Paris. 1611, fol. It is just as easy to believe that birds grow upon trees as that they are produced from rotten wood, so that the publicandre of Scaligory seems to heave conducted him but a little was havoud that that they are produced from rotten wood; so that the philosophy of Scaliger seems to have conducted him but a little way beyond the region of absolute credulity.

Boyd.

Boyce.

canon of Ross, of whom we have already presented our readers with a copious notice. While the learned archdeacon was engaged in translating the work into prose, another individual was engaged in the more formidable task of translating it into verse. A copy of this metrical version, containing about 70,000 lines, is preserved in the library of the university of Cambridge: a leaf seems to be wanting at the beginning, and the manuscript has suffered some other mutilations. The name of the versifier does not appear, nor has it been ascertained from any other document; but we learn from the prologue, that his labours, like those of Bellenden, were intended for the benefit of the young monarch. From the concluding lines, it is ascertained that he began his task in April 1531, and concluded it in September 1535. His verses are not distinguished by any considerable degree of energy or elegance, and the writer is chiefly to be commended for his perseverance. The prologue, which is unfortunately mutilated, contains an account of his motives for engaging in this laborious undertaking: it is conducted in the form of a dialogue between the translator and a certain lady, who is probably some allegorical personage. The following is perhaps the most curious passage which it contains:-

> Bot yit, scho said, I dreid in my intent That to his grace it be ovir eloquent; For quhy the termis poleist ar perfyte Of eloquence, in rycht plesand indyte, In Latene toung sententiouslie and schort, Quhilk for to heir is plesand and confort. Madame, I said, quha wes it drew that storie? Ane man, scho said, of sic hie laud and glorie, In Albione sen stories wes begun, Wes nevir nane sic amang our poetis fun. Madame, I said, quhat is that mannis name? Ane Hector Boyis, said scho, of nobill fame, Maister in art, doctor in theologie, In all science ane profound clerk is he. Madame, I said, now tell me or ye ga, Quhat is the caus that ye commend it sua? That sall I do, quoth scho, and yow wald heir. Our old storeis befoir thir mony yeir, Tha war distroyit all with Inglismen In Wallace weir, as it is eith to ken: Syne efterwart quhen that the wreit the storie, Ald eldaris deidis to put into memorie Tha maid tha bukis, thair tractatis, and thair tabilis, Part be ges, and part be fenzeit fabillis, Part tha fand in ald bladis of bukis, Part in lous quairis, liand wer in nukis: Tha tuke sic cuir sic thingis to considder, Syne in ane volume pat thame altogidder, Without ordour, fassoun, or effect; Mikill wantit, and all the lave suspect. Madame, said I, now gar me vnderstand Into quhat place that he tha stories fand. That sall I do, than said scho, with gud will. Intill ane place callit Ecolumkill, Ane abbai sumtyme of authoritie, In Iona yle, within the occident se, Quhilk oft syis had of kingis corps the cuir; Lang of the ald thair wes thair sepultuir: And thair wes keipit thair storeis and bukis, As in this libell yow sall see quhen yow luikis: And in that place thair wes thir stories fand, Sum in lows quairis, and uther sum weill band, As Beid, Turgot, and Weremund alsua, Corneill Campbell, and mony uther ma, All tell and fynd ane fassoun and effect, In ornat spech, and nothing to suspect. And for this caus I haif socht to ye heir; Hartlie as now thairof, I ye requeir, Translait this libell in our mother toung, And preis ye nocht my purpois to impugn.

The kingis grace I knaw is nocht perfyte In Latyn toung, and namelie in sic dyte; It will be tedious, that dar I tak on hand, To reid the thing he can not vnderstand: War it translatid in our vulgar toung, Out throw that realme the rumor [sould be roung.]

In the year 1528, soon after the publication of his history, Boyce took the degree of D.D. at Aberdeen; and on this occasion the magistrates voted him a present of a tun of wine when the new wines should arrive, or, according to his option, the sum of twenty pounds to purchase a new bonnet. He appears to have survived till the year 1536; for on the 22d of November in that year, the king presented John Garden to the rectory of Tyrie, vacant by the death of "Mr Hector Boiss." He died at Aberdeen, and, according to the most probable conjecture, he had then attained or at least approached the age of seventy.

(D. I.)

BOYD, MARK ALEXANDER, a remarkable scholar and soldier, son of Robert Boyd of Pinkell in Ayrshire, and grandson of Robert Boyd, great chamberlain of Scotland, was born 13th January 1562. He lost his father in early life, and was educated by his uncle the learned James Boyd of Trochrig, "Tulchan," archbishop of Glasgow. His temper, however, was so violent that he soon quarrelled with his teachers, and abandoning his studies altogether, sought preferment at the court. Among the wildest spirits of that stormy period, the intolerable fierceness of his temper made it convenient for him to retire from Scotland and seek his fortune in France. He reached Paris with a small stock of money, which he soon lost in gaming. From Paris he went to Orleans, where he studied civil law under Robertus. The fame of Cujas next attracted him to Bourges. From Bourges he was driven by the plague to Lyons, and thence to Italy. On returning to France he was engaged to instruct a young nobleman, with whom, when the wars of the League broke out, he joined the Catholic party, though himself a Protestant. When the campaign terminated in 1588, he went to Toulouse and resumed his legal studies, which were speedily interrupted by an outbreak of bigotry on the part of the inhabitants, who, taking him for a Protestant, seized and threw him into prison. On his release he withdrew to Bordeaux. Till 1595 he led an unsettled life, sometimes studying, more frequently engaged in war. He found time, however, in 1592 to publish at Antwerp a volume of Latin poems, which he dedicated in a fulsome preface to James VI. He ultimately retired to his birthplace, where he died April 10. 1601. The best of his writings are the Epistolæ Heroidum, and the Hymni, which are to be found in the Deliciæ Poetarum Scotorum, Amsterdam, 1637, tom. i. p. 142. The diction of his poems, though copious, is far from being classical, and his sentiments, sometimes lofty and noble, are more frequently coarse and impure. The finest of his poetical pieces is that entitled The Tears of Venus on the Death of Adonis. The MSS. of his unpublished works are preserved in the Advocates' Library at Edinburgh.

Boxo, Zachary, a learned and pious clergyman of the Scottish Church, was born towards the end of the sixteenth century, and died in 1653 or 1654. He was for many years regent in the college of Saumur in France, but returned to his native country in 1621, to escape the persecution of the Protestants. In 1623 he was appointed minister of the Barony church in Glasgow, and held the office of rector of the university in the years 1634, 1635, and 1645. To his munificence the university is mainly indebted for the erection of its present buildings. Besides his library and MSS., he bequeathed to it the half of his fortune, a sum amounting to L.20,000 Scots. His bust over the gateway within the

¹ This line, which is scarcely intelligible, ought perhaps to have stood thus:—
All hail and fyne in fassoun and effect.

² Kennedy's Annals of Aberdeen, vol. ii. p. 367.

³ Hailes's Sketch of the Life of Mark Alexander Boyd, 4to. M'Crie's Life of Melville vol. i. p. 85.

Boyer.

court commemorates his important benefactions. The number of his published works was considerable, and 86 of his MSS. are said to be preserved in the library of Glasgow College. His best known works are The Last Battel of the Soule in Death, 1629, of which a new edition, with a biography by Mr Neil, was published at Glasgow in 1831; Zion's Flowers, 1644. the English Academie, and Songs of Zion. His poetical compositions are not without some merit, though the remarkable eccentricity of some of them has generally made them a source of amusement rather than of edification. The common statement that he made the printing of his metrical version of the Bible a condition of the reception of his grant to the university, is a mistake.

BOYER, a kind of Flemish sloop.

BOYER, Abel, a well-known lexicographer and historiographer, born at Castres in France in 1664. Upon the revocation of the edict of Nantes, he went first to Geneva, and then to Francker, where he finished his studies. Finally he came to England, where he soon acquired such a proficiency in the English language, that he became an author of considerable note, and was employed in writing several periodical and political works. He had for many years the principal management of a newspaper called the Postboy; and he likewise published a monthly work entitled the Political State of Great Britain. He wrote a Life of Queen Anne in folio; a History of William III. in 3 vols. 8vo; and Annals of the Reign of Queen Anne, in 11 vols. 8vo But he is best known by his Dictionary and Grammar of the French Language, which are still reckoned good in their kind. He died at Chelsea in 1729.

BOYER, Alexis, a distinguished French surgeon, was born on the 1st of March 1757, at Uzerches in the Limousin. His father was in the humble station of a tailor; and the son received the elements of a medical education in the shop of a barber-surgeon in a provincial town. His early talents induced his friends to procure his removal to Paris, where he had the good fortune to attract the notice of his two distinguished masters Louis and Desault; and his unwearied perseverance, his anatomical skill, and finally his dexterity as an operator, became so conspicuous, that at the age of thirty-seven he obtained the appointment of second surgeon to the Hôtel Dieu of Paris, and was elected professor of operatic surgery in L'École de Santé. This latter appointment he soon exchanged for the chair of clinical surgery; a department in which his manual dexterity and his admirable lectures on surgical diseases gained him the highest reputation, and introduced him to extensive practice. Perhaps no French surgeon of his time thought or wrote with greater clearness and good sense than Boyer; and while his natural modesty made him distrustful of innovation, and somewhat tenacious of established modes of treatment, he was as judicious in his diagnosis, as cool and skilful in manipulating, as he was cautious in forming his judgment on individual cases.

In 1805 Napoleon nominated him imperial family surgeon; and, after the brilliant campaigns of 1806-7, made him a member of the legion of honour, and conferred on him the title of Baron of the Empire, with a salary of 25,000 francs (L.1042). On the fall of Napoleon, the modest merits of Boyer secured him the favour of the succeeding sovereigns of France, and he was consulting-surgeon to Louis XVIII., to Charles X., and to Louis Philippe. In 1835 he succeeded Deschamps as surgeon-in-chief to the Hôpital de la Charité, and was chosen a member of the Royal Academy of Sciences of the Institute of France; while various scientific, national, and foreign societies enrolled him in their lists. But honours and emoluments could not consoie Boyer for the loss of a beloved wife. From the period of her death his health began visibly to decline; and he terminated his mortal career on November 23. 1833, at the age of seventy-six.

Boyer was of a cheerful temper, unassuming and simple in his manners, and studied a genteel economy which enabled him to exhibit many traits of generosity to others. His two great works are, Traité complet de l'Anatomie, in 4 vols. 8vo, published in 1797-99; of which a fourth edition appeared in 1815; and Traité des Maladies Chirurgicales, et des operations qui leur conviennent, in 11 vols. 8vo, 1814-26. Of this work a new edition called the 5th, with additions by M. Ph. Boyer, in 7 vols., was published in 1844-53. (T. S. T.)

BOYER, Jean Baptiste, an eminent French physician, born at Marseilles in 1693. He devoted a long life to the special investigation and treatment of contagious epidemics with a courage and success which have rarely been surpassed. On the last appearance of the plague in western Europe in 1720, he was one of the physicians sent from Paris by the government to succour the inhabitants of his native city, then visited by this great calamity. The fearless zeal and ability which he displayed on that occasion, procured him a pension and the title of physician in ordinary to the king. Much of his subsequent life was spent in similar expeditions, devoted to philanthropy, wherever pestilential epidemics prevailed: and the value of the services of Boyer were fully acknowledged at Paris, Trêves, Beauvais, Montagne, Brest, and at several places in the Spanish peninsula.

He died in 1768. His writings are not numerous: the best known are his good Account of the Plague at Marseilles in 1720, and his Observations on the Epidemic that prevailed at Beauvais, published at Paris in 1750. (T.S.I.)

BOYLE, CHARLES, Earl of Orrery in Ireland, and Baron of Marston, in the county of Somerset, second son of Roger second Earl of Orrery, was born at Chelsea in 1676. He was educated at Christ Church, Oxford, and soon distinguished himself by his learning and abilities. Like the first Earl of Orrery, he was an author, a soldier, and a statesman. He translated Plutarch's life of Lysander; and published an edition of the epistles of Phalaris, which engaged him in the famous controversy with Bentley. See ATTER-BURY. He was three times member for the town of Huntingdon; and on the death of his brother, Lionel Earl of Orrery, in 1703, he succeeded to that title. He entered the army, and in 1709 was raised to the rank of major-general, and sworn one of her Majesty's privy-council. At the battle of the Wood he acted with distinguished bravery. He was appointed the queen's envoy to the states of Brahant and Flanders; and having discharged this trust with ability, he was created an English peer, as Baron of Marston, in Somersetshire. He received several additional honours in the reign of king George I.; but having had the misfortune to fall under the suspicion of the government he was committed to the Tower, where he remained six months, and was then admitted to bail. On a subsequent inquiry, it was found impossible to criminate him, and he was discharged. He died, after a slight illness, on the 28th of August 1731. his tutor, Atterbury, he probably owed in some degree his relish for the writings of the ancients. Medicine likewise was one of his favourite studies. This peer also wrote a comedy, entitled As you find it; and after him was named the orrery, an astronomical instrument invented by Graham.

BOYLE, John, Earl of Cork and Orrery, a nobleman distinguished for his literary attainments, was the only son of Charles Earl of Orrery, and was born January 2.1707. He was educated at Christ Church College, Oxford; and was led by indifferent health, and many untoward accidents, to cultivate in retirement his talents for literature and poetry. Of these he has left several favourable specimens. He translated the Letters of Pliny the Younger, with various notes, for the use of his eldest son, published in 1751, 2 vols. 4to. He also published a Life of Swift, in several letters addressed to his second son; and Memoirs of Robert Cary, Earl of Monmouth, from a manuscript presented to him by

Boyle.

Boyle. a relation. He died November 16. 1762. His letters from Italy did not appear until 1774, when they were edited, with his life prefixed, by the Rev. J. Duncombe.

BOYLE, Richard, one of the greatest statesmen of the seventeenth century, generally styled the Great Earl of Cork, was the youngest son of Mr Roger Boyle, and was born at Canterbury, October 3.1566. He studied at Benet College, Cambridge, and afterwards became a student in the Middle Temple. Having lost his parents, and being unable to support himself in the prosecution of his studies, he became clerk to Sir Richard Manwood, chief baron of the exchequer; but finding this employment little likely to improve his fortune, he went to Ireland. He was then about twenty-two years of age, graceful in person, and possessing many accomplishments, which enabled him to render himself useful to some of the principal persons employed in the government. In 1595 he married one of the daughters and co-heiresses of William Apsley. This lady died four years afterwards, leaving him a landed estate of L.500 a-year. In consequence of various services, and the great ability he displayed, he gradually rose to the highest offices; and in 1616 he was created by King James I. Lord Boyle, Baron of Youghall in the county of Cork. Four years later he was created Viscount Dungarvan and Earl of Cork; and in 1631 he was appointed lord-treasurer of Ireland, an honour that was made hereditary in his family. He particularly distinguished himself by the noble stand he made when the great rebellion broke out in Ireland in the reign of Charles I., acting with as much bravery and military skill as if he had been trained from his infancy to the profession of arms. Having turned the castle of Lismore, his principal seat, into a fortress, he immediately armed and disciplined his servants and Protestant tenants; and, with their assistance, and a small army, raised and maintained at his own expense, which he put under the command of his four sons, he defended the province of Munster, and took several strong castles. During this time he paid his forces regularly; and when all his money was exhausted, he converted his plate into coin. He died on the 15th of September 1644.

BOYLE, Richard, Earl of Burlington and Cork, son of the former, was born at Youghall in October 1612. He greatly distinguished himself by his loyalty to Charles I., whom during his troubles he supplied both with money and troops; but at last he was obliged to compound for his estate. He contributed all in his power to the Restoration; and by Charles II. he was created Earl of Burlington or Bridlington in 1663. He died in January 1697-8, aged eighty-six.

BOYLE, Robert, one of the greatest and best of modern philosophers, was the seventh son and fourteenth child of Richard Earl of Cork, and was born at Lismore castle in the province of Munster, Ireland, January 25. 1626-7. He acquired the first rudiments of learning in his father's house, being taught to speak Latin by one of the earl's chaplains, and French by a native of the country residing in the In 1635 his father sent him to be educated at Eton school, where Sir Henry Wotton, the earl's friend, was then provost. Whilst at Eton several extraordinary accidents befel him, of which he has given us an account. One was the fall of his chamber while he was in bed; when he must infallibly have been suffocated by the dust as he lay beneath the rubbish, but for his presence of mind in covering his head with the sheet, which enabled him to breath without difficulty. Soon afterwards, when he was riding, his horse suddenly reared and fell backwards, when he would certainly have been crushed but for his timely dexterity in disengaging himself from the animal.

He remained at Eton between three and four years; and then was placed as a private pupil with Mr Douch, rector of Stalbridge in Dorsetshire, a property recently purchased by the earl. In 1638 he attended his father to London, and remained with him at the Savoy, till the marriage of his brother Francis

with Mrs Elizabeth Killigrew; and immediately afterwards, the two brothers proceeded to the Continent, accompanied by M. Marcomb, a Frenchman, who was tutor to Mr Boyle. Landing at Dieppe, they passed by Rouen to Paris, and thence to Lyons; and then continued their journey to Geneva, where the family of their travelling companion resided. Here young Boyle resumed his studies in the mathematics, of which he had previously acquired some knowledge.

After residing a year at Geneva, in September 1641 he travelled through Switzerland and the country of the Grisons; then passing by Bergamo, Brescia, and Verona, he arrived at Venice, where he made a short stay. He spent the winter at Florence, employing his spare hours in reading the modern history of Italy, and in studying the works of Galileo, who died near Florence during Mr Boyle's residence there. He also acquired the Italian language, though he never spoke it so fluently as French, of which he was a perfect master.

About the end of March 1642 he went to Rome; and after visiting several of the principal cities of Italy, he arrived at Marseilles. Here he received intelligence of the Irish rebellion; and after experiencing considerable pecuniary difficulties through the loss of a remittance, in consequence of which the party were obliged to retrace their way to Geneva, he at length reached England in 1644. His father was then dead, but he had left him the manor of Stalbridge, as well as considerable property in Ireland; though during that period of public agitation he derived little benefit from them. He procured, however, from the powers in being, protection for his estates in the two kingdoms.

In March 1646 he retired to his manor at Stalbridge, where he chiefly resided till May 1650. He made occasional excursions to London and to Oxford; and in February 1647 he paid a short visit to Holland. During his retirement at Stalbridge he engaged diligently in study, devoting his attention more particularly to natural philosophy and chemistry. He omitted no opportunity of making the acquaintance of persons distinguished by their talents and learning, and to such he was always a ready and generous assistant, and maintained with them a constant correspondence. Boyle was also one of the first members of that small society of learned men, who, in consequence of the unsettled state of the times, held their meetings with great privacy, first at London, and afterwards at Oxford, for the purpose of discussing and investigating experimental philosophy, and other subjects of liberal inquiry, exclusive of re-ligion and politics. They styled themselves the Philosophic College; and after the Restoration, they were incorporated under the name of the Royal Society.

In the summer of 1654 Boyle took up his residence at Oxford, in order that he might pursue his studies to greater advantage; and here he found himself surrounded by many learned friends, such as Wilkins, Wallis, Ward, Willis, Wren, and others, who had resorted thither for the same reasons as himself. It was here that he made his improvements on the air-pump, and by numerous experiments with this instrument he was enabled to discover several qualities of air, and to lay the foundation of a satisfactory theory of its nature. He declared against the philosophy of Aristotle, as being conversant more with words than with things, and as giving the inventions of men for indubitable proofs, instead of building upon observation and experiment. zealous for the experimental method of investigation, that although the Cartesian philosophy was become the subject of general attention, he could not for many years be persuaded to read the works of Descartes, lest he should be diverted by ingenious theories from carrying out the Baconian system of experimental inquires to which he had devoted himself. But philosophy, and inquiries into nature, though they engaged his attention deeply, did not occupy it entirely. He still continued his critical and theological studies; and

Boyle. in these he had the assistance of several eminent scholars, such as Pococke, Hyde, and Clarke, all distinguished orientalists. He was also intimate with Dr Thomas Barlow, the Bodleian librarian, and subsequently Bishop of Lincoln, a man of various and extensive learning. In 1659 Boyle came to know the distressed circumstances of Sanderson, afterwards bishop of Lincoln, who lost all his preferments on account of his attachment to the royal party, and he conferred upon him a pension of L.50 a-year, to encourage him in writing his "Cases of Conscience."

On the Restoration, Boyle was very favourably received at court. He was solicited by the Lord Chancellor Clarendon to enter into holy orders, but shrunk from the responsibility; believing, moreover, that whatever he wrote in the service of religion would have greater weight as coming from a layman. He chose, therefore, to pursue his philosophical studies in such a manner as might conduce to the support of religion, and began to communicate to the world the fruits of these studies. The first of these were printed at Oxford in 1660, in 8vo, under the title of New Experiments, Physico-mechanical, touching the Spring of Air and its Effects; and Seraphic Love, or some Motives and Incentives to the Love of God. Certain physiological essays and other tracts, in 4to, appeared in 1661; and in 1662, the Sceptical Chemist, which was reprinted about 1679, in 8vo, with additional experiments and notes.

In 1663 the Royal Society was incorporated by letters patent, and Boyle was appointed one of the council. had been principally concerned in the foundation of that learned society, and through life he continued one of the most useful and industrious of its members. In 1663 he published Considerations touching the usefulness of Experimental Natural Philosophy, 4to, and Experiments and Considerations upon Colours; with Observations on a Diamond that shines in the Dark, 8vo. This treatise, which is full of curious and useful remarks on the hitherto unexplained doctrine of light and colours, may be said to have led the way to that more full and ample development of the subject which was reserved for the genius of Newton. In the same year appeared his Considerations on the Style of the Holy Scriptures, 8vo, being an extract from a larger work, entitled An Essay on Scripture, afterwards published by his friend Sir Peter Pett. In 1664 he was elected into the company of the royal mines, and all this year he was engaged in the prosecution of various good designs, which prevented his publishing anything. The year following appeared Occasional Reflections upon several Subjects, 8vo, addressed to Sophronia (his sister the Viscountess Ranelagh). In ridicule of these discourses, Dean Swift wrote A Pious Meditation upon a Broomstick, in the style of the Honourable Mr Boyle. "To what a height," said Lord Orrery, "must the spirit of sarcasm arise in an author, who could prevail on himself to ridicule so good a man as Mr Boyle?" The same year he published an important work, entitled New Experiments and Observations upon Cold, 1665, 8vo; and in 1666, Hydrostatical Paradoxes made out by new Experiments, 8vo; and also the Origin of Forms and Qualities, according to the Corpuscular Philosophy. Besides these, both in this and the former year, he communicated to the Royal Society several curious and excellent short treatises, which are preserved in the Philosophical Transactions.

In 1668 Boyle settled in London, in the house of his sister, Lady Ranelagh, in Pall-Mall. In the following year he published A Continuation of New Experiments, touching the Weight and Spring of the Air; to which is added, A Discourse of the Atmospheres of Consistent Bodies. He also revised and made additions to several of his former works, some of which were now translated into Latin. About the same time he published his Tracts about the Cosmical

Begions, and the Bottom of the Sea; to which is prefixed, Boyle. an Introduction to the History of Particular Qualities. This book occasioned much speculation, as it contained a vast treasure of knowledge, founded upon actual experiments, or arguments justly drawn from them, instead of that conjectural philosophy which in the beginning of the seventeenth century had been so much in fashion. In 1671 he published Considerations on the Usefulness of Experimental and Natural Philosophy, (part second), 4to; and, A Collection of Tracts upon several useful and important points of Practical Philosophy, 4to; which were received as new and valuable gifts to the learned world. An essay concerning the Origin and Virtues of Gems, 8vo, appeared in 1672; also, A collection of tracts upon the relation between flame and air, and several other useful and curious subjects; besides which he furnished, in this and the former year, a great number of short dissertations upon a variety of topics, addressed to the Royal Society, and inserted in their Transactions. Essays on the Subtility and determinate Nature of Effluvia, to which were added a variety of Experiments on other Subjects, came out in 1673, 8vo. A collection of tracts upon the Saltness of the Sea, the Moisture of the Air, the Natural and Preternatural State of Bodies, to which is prefixed a dialogue concerning Cold, was published in 1674, 8vo. The Excellency of Theology, compared with Philosophy, appeared in 1673. This discourse was written in 1665, when the Great Plague which then raged in London obliged the author to wander from place to place in the country, where he had little opportunity of consulting books. A Collection of Tracts, containing Suspicions respecting Hidden Qualities of the Air, with an appendix, touching Celestial Magnets, Animadversions upon Hobbes's Problem about a Vacuum, and a Discourse of the Cause of Attraction and Suction, was published in 1674. Some Considerations about the Reconcileableness of Reason and Religion, by a Layman, to which is annexed a discourse about the Possibility of the Resurrection, appeared in 1655. Amongst the papers which he communicated to the Royal Society this year, one was entitled An Experimental Discourse of Quicksilver growing hot with Gold; and another relating to the same subject; each of which contained important discoveries.

In 1676 he published Experiments and Notes about the mechanical origin or production of Particular Qualities, in several discourses on a great variety of subjects, and among the rest on electricity. In 1678 he communicated to Dr Hooke a short memorial of some observations made upon an artificial substance that shines without any preceding illustration; which that philosopher published in his Lectiones Cutlerianæ. His historical account of a degradation of gold produced by an anti-elixir, is looked upon as one of the most remarkable pieces that ever fell from his pen. The regard which Sir Isaac Newton entertained for Boyle may be seen in a letter which he wrote to him, towards the close of this year, stating his sentiments of that ethereal medium which he afterwards considered in his Optics as the cause of gravitation. This letter is given in the Life of Boyle by Dr Birch.

In 1680 he published the Aerial Noctiluca, or some new phenomena, and a process of a factitious self-shining substance, 8vo. This year the Royal Society, as a proof of their sense of his great worth, and of the services which he had rendered the society, elected him their president; but being extremely sensitive in regard to oaths, he declined the honour. He published a discourse of Things above Reason, inquiring, whether a philosopher should admit any such, 1681, 8vo; New Experiments and Observations upon the icy Noctiluca, to which is added a chemical paradox, grounded upon new Experiments, 1682, 8vo; and a continuation of New Experiments, Physico-mechanical, touching the Spring and Weight of the Air, 1682, 8vo. In 1683 he

Boyle.

Boyle.

tion to the making of fresh water out of salt; but in 1684 he published Memoirs for the natural history of Human Blood, especially the spirit of that liquor, 8vo; and Experiments and Considerations about the Porosity of Bodies. In 1685 he published Short Memoirs for the natural experimental history of Mineral Waters, with directions as to the several methods of trying them; an Essayon the great Effects of even languid and unheeded motion, which was received with great and general applause; a Treatise of the Reconcileableness of specific Medicines to the Corpuscular Philosophy, to which is annexed a Discourse about the Advantages of the use of Simple Medicines, 8vo; and a theological tract of the high veneration Man's intellect owes to God, peculiarly for his wisdom and power, 8vo. In the beginning of the succeeding year came out his Free Inquiry into the vulgarly received notion of Nature; and in 1687 he published the martyrdom of Theodora and Didymia, a juvenile performance. His Disquisition about the final causes of natural things, in 8vo, appeared in 1688.

He now began to find that his health and strength, not-withstanding every care, gradually declined. He no longer communicated particular discourses or new discoveries to the Royal Society, because it could not be done without withdrawing his thoughts from occupations which he thought of still greater importance. In order the more steadily to attend to these, he resigned his post of governor of the corporation for propagating the gospel in New England; and even went so far as to signify to the world, by public advertisement, that he could no longer receive visits as usual. Among the other works which by this means he gained time to finish, was a collection of elaborate processes in chemistry, which, as he stated in a letter to a friend, he left "as a kind of hermetic legacy to the studious disciples of that art." Besides these papers, he left behind him many relating to chemistry.

He published some other works, as Medicina Hydrostatica, or, Hydrostatics applied to the Materia Medica, 1690, 8vo; The Christian Virtuoso, to which is subjoined, A Discourse about the Distinction that represents some Things as above Reason, but not contrary to Reason; and the first chapters of a discourse entitled Greatness of mind promoted by Christianity. Lastly, he published in the spring of 1691, Experimenta et Observationes Physica, treating of several subjects relating to natural philosophy, in an experimental way, 8vo.

About the beginning of summer he began to feel such an alteration in his health as induced him to think of settling his affairs; and on the 30th December 1691 he departed this life, in the sixty-fifth year of his age. He was buried in St Martin's in the Fields, Westminster; and his funeral sermon was preached by Dr Gilbert Burnet, bishop of Salishury.

The edition of the New Testament in the Malayan tongue was undertaken at Boyle's expense, and sent over all the East. He munificently rewarded the person who translated Grotius's book De Veritate into Arabic; and he was at the charge of a whole impression, which he took care to have distributed in all the countries where that language was understood. It was his intention to have printed an impression of the New Testament in Turkish; but the design was carried out by the Levant Company. Boyle, however, contributed largely towards it. He expended L.700 on an edition of the Scriptures in Irish, and contributed liberally to the impression of the Welsh Bible. He gave, during his life, L.300 to advance the design of propagating the Christian religion in America; and as soon as he heard that the East India Company were entertaining propositions for a similar design in the East, he sent a donation of L.100. His various charities amounted altogether to upwards of L.1000 a-year.

Of his merits as an inquirer into nature, Boerhaave re-

marks, that "Boyle, the ornament of his age and country, succeeded to the genius and inquiries of the great Chancellor Verulam;" to which he adds—"To him we owe the secrets of fire, air, water, animals, vegetables, fossils; so that from his works may be deduced the whole system of natural knowledge." This may now appear extravagant; but at the time it was considered a just tribute to his extraordinary merit and indefatigable perseverance.

In his person Robert Boyle was tall, slender, and of a pale countenance. His constitution was extremely delicate; and he was so apprehensive of the effects of cold, that he was guided by the thermometer in fixing upon one of his numerous cloaks to wear abroad. Though labouring for nearly forty years of his life under every disadvantage of bodily weakness and depression of spirits, his ardour in the cause of science suffered no abatement, as amply testified by the extent and importance of his various productions. He had likewise a weakness in his eyes, which rendered him extremely apprehensive of such distempers as might affect them. As to life itself, he set that just value on it which became a philosopher and a Christian. He was never married, although he had at least one opportunity of making an advantageous connection, since we find from a letter of Dr John Wallis to him, dated Oxford, 17th July 1669, that an overture had been made to him in regard to the Lady Mary Hastings, sister to the Earl of Huntingdon.

The following is a list of his posthumous works:—1. The General History of the Air designed and begun; 2. General Heads for the Natural History of a Country, for the use of Travellers and Navigators; 3. A paper of the Hon. Robert Boyle's, deposited with the secretaries of the Royal Society, being an account of his making the Phosphorus, September 30, 1680; 4. An account of a way of examining Waters as to Freshness or Saltness; 5. A free Discourse against customary Swearing, and a Dissuasive from Cursing, 1695, 8vo; and 6. Medicinal Experiments, or a Collection of choice Remedies, &c., 1698, 12mo. Editions of all his works have been printed at London, in five volumes folio, and six volumes 4to.

BOYLE, Roger, Earl of Orrery, fifth son of the great Earl of Cork, was born in April 1621. He distinguished himself while a student at Dublin College, and afterwards made the tour of France and Italy. On his return he was created Lord Broghill, through the interest of the Earl of Strafford. Shortly afterwards he married Margaret Howard, sister to the Earl of Suffolk; and passing over to Ireland with his bride, he found the country in a state of rebellion, and assisted his father in opposing the insurgents. Upon the execution of the king, he retired to his seat at Marston in Somersetshire; but his spirit could ill brook this state of inactivity, and he therefore resolved to cross the seas, and apply to Charles II. for a commission to raise forces to restore the monarchy and recover his own estate. Under the pretence of visiting Spa for his health, he proceeded as far as London, when he received a message from Cromwell, then general of the parliamentary forces and a member of the committee of state, intimating his intention to wait upon him. Presently Cromwell himself entered the room, and after the exchange of a few civilities, told Lord Broghill that the committee were apprised of his design; and when his lordship assured him that the intelligence was false, Cromwell produced copies of several of his confidential letters, which reduced him to the necessity of asking Cromwell's pardon, and requesting his advice in such a conjuncture. Cromwell told him, that though he had hitherto been a stranger to his person, he was not so to his merit and character; that he had heard how gallantly his lordship had behaved in the Irish wars; and he concluded by offering him the command of a general officer, exempt from all oaths and engagements; adding that he should not be obliged to draw his sword against any but the Irish rebels. Lord Broghill, greatly surprised at so unexpected an offer, requested some time for deliberation. But Cromwell briskly told him that he must determine instantly; that he himself

Boyle

Boyse.

Boyle's was about to return to the committee, who were still sitting; Lectures. and that if his lordship rejected their offer, they had determined to send him to the Tower. Broghill, finding that his liberty and life were in the utmost danger, pledged his honour that he would faithfully serve against the Irish rebels; and accordingly, by Cromwell's instructions, he passed over into Ireland, where by many important services he fully justified the opinion which Cromwell had conceived of him. Having raised a troop of horse, it was soon increased to a regiment of 1500 men, and these he led into the field against the rebels. He was speedily joined by Cromwell, who placed the highest confidence in his new ally, and found him of the greatest value to the interest of the commonwealth.

When Cromwell became Protector, Lord Broghill was made one of his privy council, and admitted to great intimacy and confidence. It is said that the latter formed a project for engaging Cromwell to restore the old constitution, by a match between Charles II. and the Protector's daughter. Cromwell, who at first seemed to think it not unfeasible, soon perceived the difficulties which it involved, and told Broghill that he thought his project impracticable: "For," said he, " Charles can never forgive me the death of

his father.'

On the death of Cromwell, Lord Broghill continued attached to his son Richard, till, seeing that the weak nature of that amiable man would infallibly bring on his fall, he deemed it imprudent still to cling to one whom he could not save, and accordingly retired to his command in Ireland, where affairs shortly after took a turn extremely favourable to the design of the king's restoration. Lord Broghill was not a little instrumental in bringing about that event; and, in consideration of his eminent services, Charles created him. Earl of Orrery, September 5. 1660. He was soon after made one of the lords justices of Ireland; and his conduct, whilst at the head of affairs in that kingdom, was such as to add greatly to the general esteem in which his character was previously held.

His active and toilsome course of life at length brought on disease and infirmity; but, notwithstanding, he went over to England in 1665, at the king's desire, and mediated with success in a serious misunderstanding which existed

between the king and the Duke of York.

On his return to Ireland, Lord Orrery, by his prudent and skilful measures, rendered abortive the scheme of a descent upon Ireland by the Dutch and French, planned by the Duke de Beaufort, admiral of France.

About this time a quarrel with his old friend the Duke of Ormond, arising from mutual jealousies, became so serious that the disputants resorted to England to defend their respective interests. This quarrel, though of a private beginning, became at last of a public nature. Lord Orrery was impeached, but defended himself so well that the prosecution failed. He lost, however, his public employments; but, retaining the king's favour, still came frequently to court, and was often consulted on affairs of importance. His last voyage to England was for the purpose of obtaining medical advice; but his disease, which was gout, proved mortal, and he expired on the 16th of October 1679, in the fifty-ninth year of his age. Lord Orrery was the author of several works, chiefly dramas and poems, now forgotten. Walpole remarks "that he never made a bad figure but as a poet." As a soldier, his valour was distinguished, his stratagems and tact were remarkable; as a statesman, it is sufficient to say that he possessed the confidence of Cromwell; and his credit ever stood high for integrity, and for generous fidelity as a friend.

BoxLe's Lectures, a course of eight sermons or lectures preached annually, and founded by the Honourable Robert Boyle, whose design, as expressed in a codicil annexed to his will in 1691, was to prove the truth of the Christian religion against infidels, without descending to any controversies among Christians, and to answer new difficulties or

scruples that might from time to time arise. For the support of this lecture, he assigned the rent of his house in Crooked Lane to some learned divine within the bills of mortality, to be elected for a time not exceeding three years, by Archbishop Tennison and others. But the fund proving precarious, the salary was ill paid; and to remedy this inconvenience, the archbishop procured a yearly stipend of L.50 for ever, to be paid quarterly, charged on a farm in the parish of Brill in the county of Bucks. To this appointment we are indebted for many elaborate defences both of natural and revealed religion.

BOYLE, or ABBEY BOYLE, a town and parish of Ireland, in the county of Roscommon and barony of the same name, on the river Boyle, an affluent of the Shannon, 94 miles W.N.W. of Dublin. It has a church, four chapels, barracks, market-house, bridewell, union-poorhouse, dispensary, and savings-bank. Previous to the Union it returned two members to the Irish parliament. It has some trade in grain, butter, and flax. Considerable remains of the abbey, an edifice of the latter part of the twelfth century, are still to

be seen. Pop. (1851) 3463.

BOYNE, a river of Ireland, rising in the Bog of Allen, near Carbery in Kildare, and flowing in a N.E. direction, passes Trim, Navan, and Drogheda, and enters the Irish Sea about four miles below the last-mentioned town. It is navigable for barges of 70 tons to Navan, 19 miles from its mouth. About three miles west of Drogheda, an obelisk, 150 feet in height, marks the spot where the forces of William III. gained the celebrated victory over those of James II. on 1st July 1690, known as the "battle of the Boyne."

BOYSE, Boys, or Bois, John, one of the translators of the English Bible, was born at Nettlestead in Suffolk, January 3. 1560. He received the rudiments of learning from his father; and so precocious were his talents, that it is said he could read Hebrew at the age of five. At fourteen he was admitted of St John's College, Cambridge, where he was during ten years principal Greek lecturer. He also delivered a Greek lecture for some years at four in the morning, in his own chamber, which was frequented by many of the fellows. On the death of his father, he succeeded to the rectory of West Stowe. At the age of thirty-six he married the daughter of Mr Holt, whom he succeeded as rector of Boxworth, in Cambridgeshire, in 1596. On his quitting the university, the college gave him L.100; but his wife being a bad economist, he soon became so much involved in debt that he was obliged to sell his choice collection of books, consisting of every Greek author then extant. When James I. directed a new translation to be made of the Bible, Bois was chosen as one of the translators; and he not only executed his own portion, which was the Apocrypha, but also the part assigned to another. He was also one of the six who had met at Stationers' Hall to revise the whole; which task they performed in nine months, having each, from the company of stationers during that time, thirty shillings a-week. He afterwards assisted Sir Henry Savile in publishing the works of St Chrysostom. In 1615 Dr Lancelot Andrews, bishop of Ely, bestowed on him unasked a prebendal stall in his cathedral. He died 14th January 1643, and left a great mass of manuscripts behind him. A work of his on the text of the Evangelists and Acts was published in 1655. When a student, Boyse received from the learned Dr Whitaker three rules for avoiding those diseases which are often engendered by sedentary pursuits, viz., to read standing, not to study at a window, and never to go to bed with cold feet. By attention to these simple precepts he is said to have preserved to the last an unwrinkled brow, with a freshness of complexion and vigour of constitution very rarely to be found in advanced age.

Boyse, Samuel, an English writer of considerable ability, but scandalous character, was born in 1708, and died in great wretchedness in 1749. His poetical compositions Bozrah Bracciolini.

were numerous, and one of them, entitled The Deity, received the praises of Hervey and Fielding; but none of them have survived the test of time.

BOZRAH, a chief city of the Edomites, 80 miles N.E. of Jerusalem, and known to the Greeks and Romans under the name of Bostra. It was 24 miles to the south of Edrei, one of the capitals of Bashan. Under Alexander Severus it became the seat of a Roman colony. Till the seventeenth century it was much frequented by caravans of pilgrims on their way to Mecca, who found in it abundant supplies of water. In the town itself, which is now little more than a heap of ruins, there is still in good preservation a reservoir, 190 paces in length, 153 in breadth, and 20 feet in depth, with walls 7 feet in thickness. Immediately beyond the walls of the city is a strong castle, built by the Saracens, which is still found of use to defend the few remaining inhabitants from the incursions of Bedouin marauders.

BRA, a town of Sardinia, province of Alba, on the river Stura, 25 miles N.E. of Cuneo. It has three parish churches, a gymnasium, hospital, manufactures of silk and linen goods, and a considerable trade in corn, cattle, and wine. Pop. 11,500.

BRABANCIONES, in historians of the middle age, a kind of soldiery or commissioned banditti, who would fight for any one who could pay them. Brabant was the chief nursery of these troops—whence the name. They are frequently confounded with the Routiers, Roturiers, Ruptarii, Ruterarii, Corteraux, and others.

BRABANT, North and South, two provinces, the former in Holland and the latter in Belgium, which see.

BRABEUTES (βραβευτής). See AGONOTHETA. BRACCIOLINI, FRANCESCO, an Italian poet, born at Pistoja, of a noble family, A.D. 1566. Removing to Florence, he was admitted into the academy there, and devoted himself to literature. At Rome he entered into the service of Cardinal Maffeo Barberini, with whom he afterwards went to France. After the death of Clement VIII. he returned to his own country; and when his patron Barberini was elected pope under the name of Urban VIII., Bracciolini repaired to Rome, and was made secretary to the pope's brother, Cardinal Antonio. He had also the honour conferred on him of taking a surname from the arms of the Barberini family, which were bees; whence he was afterwards known by the name of Bracciolini dell' Api. During Urbane's pontificate the poet lived at Rome in considerable reputation, though, at the same time, he was censured for his sordid avarice. On the death of this pontiff he returned to Pistoja, where he died in 1645. There is scarcely any species of poetry, epic, dramatic, pastoral, lyric, or burlesque, which Bracciolini did not attempt; but he is principally noted for his mock-heroic poem entitled Lo Scherno degli Dei, which was published in 1618, four years before Tassoni's Secchia Rapita; yet, though the author wished to claim the merit of priority, it should be observed that Tassoni's poem was completed in 1615, and freely circulated in MS. The inferiority of Bracciolini's performance, indeed, is acknowledged, yet it obtained considerable applause. his serious heroic poems, the most celebrated is La Croce Racquistata, which by some is placed next to the works of Ariosto and Tasso, sed magno intervallo.

Bracciolini, Poggio. This eminent scholar and contributor to the restoration of classical learning, was born at Terra-Nuova, a small town near Arezzo, Feb. 11. 1380. His father (a notary) had once been possessed of considerable property, but was ruined by circumstances which have not been recorded; and Poggio, after receiving a capital education in the usual branches then taught at the university of Florence (where he studied Latin under Gio. Malpaghino, commonly called John of Ravenna), was at an early age thrown on his own resources. The inaccuracy of the commonly received opinion that he studied Greek under

the celebrated Manuel Chrysoloras, is proved by a letter Braccioof his, in which he states that he commenced his Greek studies at Rome in 1424, i.e., some years after the death of Chrysoloras.

Poggio set out for Rome in 1403, and was soon received by Pope Boniface IX. as apostolical secretary, an office of high trust; in which his talents and integrity must have been conspicuous, as he held the same situation under eight successive pontiffs. In the following year, under Innocent VII., he was able to introduce his excellent friend Leonardo Bruni of Arezzo into the office of apostolic scribe. On the death of Innocent, Italy was convulsed by the claims of rival popes; and Poggio embraced that opportunity of visiting his native country, where he received the patronage of Niccolo Niccoli of Florence, a munificent encourager of learned men, and where he remained until recalled to the apostolic secretaryship on the election of John XXII. In that capacity he accompanied the pope to the council of Constance in October 1414; and saw his master first suspended and finally deposed by the general council of the church, after they had brought to trial and executed—in defiance of the safe-conduct granted him by the emperor-the celebrated Bohemian reformer, John Huss. The deposition of the pope caused the dispersion of his officers; and though the affairs of Poggio were not in a very prosperous condition, he remained at Constance and its vicinity for a considerable time. He was a witness to the trials and execution of another martyr to the cause of reformation, Jerome of Prague; who, undeterred by the fate of Huss, presented himself before the council, and was twice tried by that body. Poggio has left us a vivid narrative of the genius and intrepidity of the martyr in his eloquent defence and terrible punishment. His admiration of the man has evidently converted the apostolical secretary into a powerful panegyrist of a condemned heretic. In a letter to his friend, Leonardo Aretino, he says:—" His voice was sweet, clear, and sonorous; his action dignified, and well adapted to express indignation, or to excite compassion-which, however, he neither asked nor wished for. He stood undaunted and intrepid; not merely contemning, but, like another Cato, longing for death. He was a man worthy to be had in everlasting remembrance."

This part of the life of Poggio is that on which his chief claim to the gratitude of posterity rests. He now devoted his leisure and his resources to rescuing from the destruction with which the barbarism of Europe had well nigh consigned them, the precious remains of classic authors; and his diligent search for ancient MSS. in the mouldering archives of religious houses in several parts of Germany, Italy, and France, which he visited for this purpose, are creditable to his industry and his taste. A great number of MSS. were collected by his own hands, sometimes transcribed by him, or were procured by his means, and deposited in the libraries of Italy, then the only part of Europe where their value was truly estimated. To Poggio's zeal we owe the recovery of seven orations of Cicero, which we shall indicate in the order in which they appear in the Barbou edition of his works. 1. Pro Roscio Comædo; 2. De Lege Agraria, ad Senatum; 3. De Lege Agr., ad Populum; 4. De Lege Ágr., ad Populum; 5. Pro C. Rabirio Perduellonis Reo; 6. In Lucium Pisonem; 7. Pro C. Rabirio Postumo. He also recovered the poem of Silius Italicus on the second Punic War; Vegetius de Re Militari; Lactantius de Ira Dei et Opificio Hominum; Tertullian; Nonius Marcellus; Ammiani Marcellini Historia; Lucretius; Columella; Julius Frontinus de Aquæductis; the eight books of Firmicus on Mathematics; Calpurnii Bucolica; Petronius Arbiter; and to the same indefatigable explorer we are indebted for bringing to light the astronomical poem of Manilius, the lyrics of Lucius Septimius, with the treatises of Caper, Eutychius, and Probus. It was also through Poggio that

Brace

Bracton.

Braccio- Nicolas of Treves recovered twelve of the comedies of Plautus, and a fragment of Aulus Gellius.

These discoveries appear from a letter of F. Barbaro to have taken place before June 14. 1417; and it may easily be conceived that these researches were a heavy drawback upon the finances of Poggio. His difficulties were increased by the unexpected death of his friend and patron Zarabella, the Cardinal of Florence, which occurred in 1417. In this dilemma he accepted an invitation to come to England from Cardinal Beaufort, Bishop of Winchester; but on arriving in London the magnificent promises of the cardinal vanished in air; and Poggio experienced the mortification of neglect among a people rude and illiterate, and utterly untinctured with the spirit of refinement that had been kindled in Italy. After spending four years in vain in England, in which a very paltry piece of preferment was all he could obtain, he returned to Italy in 1421, and again became apostolical secretary to Martin V.; and, on the death of that pontiff in 1431, to his successor Eugenius IV., who was obliged to retire to Florence, whither he was willingly followed by Poggio; but on the election of the able and excellent Nicolas V. in 1447, Poggio resumed his office of secretary at Rome. The cruelties of Pope Eugenius drew down on him the vengeance of his subjects, and he was ignominiously driven from his capital in 1433, and narrowly escaped with his life. His friends were arrested; and Poggio had the misfortune to fall into the hands of a noted condottiero, Piccinino, who compelled him to pay a large ransom for his freedom, which the narrowness of his finances rendered it very difficult for him to pay.

In 1436, Poggio, who had always steadily refused to enter into holy orders as a means of obtaining promotion, married Vaggia de Bondelmonti, daughter of a wealthy and honourable Tuscan family, with whom he lived very happily. Soon after his marriage he gave vent to his satisfaction in an elegant Latin dialogue, An seni sit uxor ducenda, in which'he maintains the wisdom of the step which he had taken. By this lady he had five sons—Pietro Paulo, Giovanni Battista, Jacopo, Giovanni Francesco, and Filippo-and a daughter, Lucretia, who married into the family of the Bondelmonti.

On the appearance of the plague at Rome in 1450, the court left the city, and Poggio withdrew to Florence, at which time he wrote his Facetiæ; a collection of stories, in the taste of that age, more remarkable for their humour than their delicacy. In 1453 he was chosen chancellor of Florence, which finally fixed his residence in his native country. He now turned his attention to the history of Florence, and composed his history of that republic; an elaborate and very eloquent work, in which he imitated Livy and other ancient historians, by explaining the secret springs of action in the characters he delineates, by speeches which he puts into their mouths. His statements are clear and well defined; and he is particularly happy in his delineation of character. It was translated into Italian by his unfortunate son Jacopo.

The works of Poggio Bracciolini have never yet been wholly published. This is to be regretted, especially with respect to his letters, which give interesting details of what he saw and heard. Many of these, from which much light might be expected on the contemporaneous state of Italy, Germany, France, and England, exist in the Ricardi Library at Florence, and other Continental collections, as we are informed by Tonelli, in the preface to his excellent translation of the life of Bracciolini by the Rev. William Shepherd, LL.D. an elegant English work, which has gone through two editions in Britain, and has been also well translated into French and German.

Poggio Bracciolini died at Florence on the 30th of October 1459, and was buried with public honours in the church of Sta Croce, next his accomplished friend Leonardo Aretino. A fine statue of him, by Donatello, exists in the cathedral of Florence.

The following is a list of his published works:—1. Dialogue on Avarice, 1431-32; 2. An Seni Sit Uxor Ducenda, 1436; 3. Oration on the Death of Niccolo Niccoli, 1437; 4. Dialogue on Nobility, 1440; 5. Oration on the Death of Lorenzo de Medici, 1440; 6. Dialogue on the Unhappiness of Princes, 1440; 7. Oration on the Death of Cardinal di Sta Croce, 1443; 8. Eulogy of Leonardo Arctino, 1444; 9. Eulogy of Cardinal Julian di Sn Angelo, 1444; 10. Inaugural Address to Pope Nicolas V., 1447; 11. On the Vicissitudes of Fortune, 1447; 12. On Hypocrisy (in which he lashes the clergy), 1447; 13. Latin Translation of Xenophon's Cyropædia which he declared a romance, not a history), 1445; 14. Latin Translation of Diodorus Siculus, 1448; 15. Liber Facetiarum, 1451; 16. Historia Deceptiva Convivialis, 1451; 17. De Miseria Humana Conditionis, 1452; 18. Translation of the Golden Ass of Apuleius (which he shows to be derived from Lucian), 1452; 19. Historia Florentina,

BRACE, that which holds anything firm, as a bandage, or a cross timber in building. In printing, it denotes a crooked line connecting two or more lines. It is also used by sportsmen for a couple or pair; as a brace of bucks, of hares, of grouse, &c. Brace literally means "arm."

Braces, in sea language, are ropes reeved through blocks at the ends of the yard-arms, for the purpose of

squaring or traversing the yards.

BRACELET, an ornament worn on the wrist. It was much used among the ancients, and was made of different materials, according to the fashion of the age and the rank of the wearer. The word is French, bracelet; which Menage derives from braceletum, a diminutive of bracile, all formed from the Latin brachium, an arm. This kind of ornament was called by the Romans armilla, brachiale occabus; and in the middle ages boga, bauga, armispatha.

Bracelets have at all times been much in use among Eastern nations; and the women frequently wear many on the same arm. Among the higher classes these are of mother of pearl, fine gold, or silver; while poorer persons use plated steel, horn, brass, copper, beads, &c.

BRACHIOPODA, Cuvier's fifth class of Mollusca.

See Mollusca.

BRACHMINS, or Brachmans. See Brahmins.

BRACHYGNATHUS, a genus of fossil fishes—the only known species of which, B. Tenuiceps, occurs in the London clay of Sheppy

BRACHYGRAPHY (βραχύς and γραφή), the art of short-hand writing. See STENOGRAPHY.

BRACKET, a kind of stay against a wall to support a shelf or the like.

Brackets, in a ship, are small crooked timbers resembling knees, fixed in the frame of the ship's head, to support the gratings. They also serve to support the gallery.

Brackets, in Gunnery, the cheeks of the carriage of a mortar. See Gunnery.

BRACKETS, in Printing. See CROTCHETS.

BRACKLEY, a market-town of Northamptonshire, sixty-three miles from London. It is situated on a slope on the north bank of the Ouse. The houses are mostly built of stone, ranged in one street, extending from the bridge up the hill. It has two churches, a handsome markethouse, an endowed free school, a hospital, and manufactures shoes and laces. Previous to the Reform Act it returned two members to parliament. Pop. in 1851, 2147.

BRACTON, HENRY, lord chief justice of England in the reign of Henry III., was probably a native of Devonshire. He was educated at Oxford, where he took the degree of doctor of laws; and about the year 1244 was made one of the itinerant judges. Ten years later he became chief justice, and had the Earl of Derby's house in London assigned him for his town residence during the minority of that nobleman. He is said to have filled this important office with singular reputation during twenty years. The time of his death is not known; but it probably occurred about the year 1273. He wrote De Le-

Brading

Bradley.

Bradford. gibus et Consuetudinibus Angliæ, which is one of the most ancient and most methodical treatises on the laws of Eng-This work is after the model of Justinian. It was printed at London in 1569, folio; and in 1640, in 4to.

BRADFORD, a parliamentary borough and markettown of England, in the west-riding of Yorkshire and wapentake of Morley, on an affluent of the Aire, 219 miles from London by rail, 30 miles W.S.W. of York, and 8 west of Leeds. In the older parts of the town the streets are generally narrow, but otherwise they are of sufficient width, and well paved and lighted. The parish church of St Peter is a structure in the perpendicular style, erected in the reign of Henry VI. There are six other churches and numerous places of worship of Presbyterians, Independents, Baptists, Methodists, Quakers, Roman Catholics, &c. The free grammar-school, founded in the reign of Edward IV., rebuilt in 1830, has a good library, and exhibitions at Queen's College, Oxford. There are many national, British, industrial, infant, and Sunday schools. There is a Baptist and an Independent theological college in the vicinity; the Methodists have also a seminary for educating the sons of their clergy. Among the public buildings are the new infirmary, erected in 1844, the Exchange of Piece Hall (a market for woollen goods), court-house, and jail. There are also a mechanics' institute, Odd Fellows' Literary institution, with a good library and news room, a savings-bank, dispensary, and numerous other charities. The first Temperance Society in England was established here. The staple manufactures of Bradford are worsted and woollen stuffs, which are in a very flourishing condition, and give employment to a great part of its population. The iron trade is also considerable, and in the neighbourhood is a plentiful supply of iron and coal. By means of the Liverpool and Leeds canal, with which it is connected by a branch, it communicates with the ports on the east and west coasts of the kingdom, and lines of railway connect it with all parts of the country. The borough is governed by a mayor, 14 aldermen, and 42 councillors, and returns two members to parliament since the passing of the Reform Act. Pop. (1851) 52,493. Market-day Thursday. The parliamentary borough includes the townships of Bradford, Manningham, Bowling, and Horton; pop. (1851) 103,778. Electors (1852) 2683. A festival is celebrated here every seventh year in honour of Bishop Blaise, said to be the inventor of wool-combing.

BRADFORD, Great, a market-town in the hundred of the same name, county of Wilts, on the Avon, 100 miles from London. It is pleasantly situated on both sides of the river, here crossed by two bridges, the old one of nine arches; the houses are built of stone, but the streets are mostly narrow. The town has a fine old church, three other churches, nine chapels, a gaol, bank, savings-bank, free and national schools, alms-house, and several charities. It has long been celebrated for the manufacture of fine broadcloths and kerseymeres. The Avon and Kennet canal facilitates its communication with Bath, Bristol, Devizes, and other towns. Pop. (1851) 4240.

BRADFORD, John, an eminent English martyr, born at Manchester in the early part of the reign of Henry VIII. Being a good penman and accountant, he became secretary to Sir John Harrington, who was paymaster of the English forces in France. Bradford at this time was gay and thoughtless, and to support his extravagance he appropriated some of the king's money; but being unable to endure the reflection of his guilt, he made restitution of the money, and relinquished his employment. About 1547, he took chambers in the Inner Temple, and began to study the law; but finding divinity more congenial to his taste, he removed the following year to Catherine-hall, Cambridge, where he applied to study with such assiduity, that in little more than a year he was admitted to the degree of master of

arts, and soon after made fellow of Pembroke-hall. Bishop Ridley, who in 1550 was translated to the see of London. now sent for him to the metropolis, and appointed him his chaplain. In 1553 he was also made chaplain to Edward VI., and became one of the most popular preachers in the kingdom. Such a reformer, however, was too dangerous to be tolerated in the succeeding reign. Accordingly he was among the earliest victims of Mary's intolerant reign. On a charge of sedition he was confined in the Tower, where he continued a year and a half. During this time he wrote several epistles, which were dispersed in various parts of the kingdom. He was afterwards removed to Southwark, and at last brought to trial before that court of inquisition in which Gardiner sat as chief, where he defended his principles to the last, in defiance of their at-tempts to effect his conversion. They condemned him to the flames, and he suffered accordingly in Smithfield, July 1. 1555. His writings, which consist chiefly of sermons, meditations, tracts, letters, and prayers, have recently been published in 12mo by the Religious Tract Society.

BRADING, a town and parish on the eastern side of the Isle of Wight, in the county of Hants, E.S.E. of Newport. The town is paved and lighted, and has a capacious but shallow harbour, which is dry at low water. It has little trade, depending chiefly on the rural inhabitants in its vicinity. It has a church, said to have been built in 1704, two dissenting chapels, a national school, and town-hall. Pop. of parish in 1851, 3046.

BRADLEY, DR JAMES, a celebrated English astronomer, was born at Sherborne in Dorsetshire in March 1692. He was educated at a school at North Leach, and at Balliol College, Oxford. As soon as he was of age to receive holy orders, the Bishop of Hereford gave him the vicarage of Bridstow; and he obtained soon afterwards the rectory of Llandewy-Welfrie in Pembrokeshire. Both these livings, however, and the hopes of further advancement in the church, he at length resigned, that he might devote himself entirely to mathematics and astronomy.

For a while he was curate of Wanstead in Essex, of which parish his uncle, Mr Pound, favourably known to the learned world for his astronomical observations, was rector. It may be imagined that the example and conversation of Mr Pound did not render Bradley fonder of his profession than before. He still continued, however, to fulfil its duties, though at this time he had made such observations as laid the foundation of those discoveries which afterwards distinguished him as one of the greatest astronomers of his age. These observations, made as it were by stealth, soon gained him the notice and friendship of the Lord Chancellor Macclesfield, Newton, Halley, and other members of the Royal Society, into which he was soon elected a member. On the death of Dr Keil in 1721, Bradley was appointed to succeed him as Savilian professor of astronomy; and for his colleague he had Halley, who was professor of geometry on the same foundation. Bradley now resigned his two livings, quitting with joy a situation in which his duty was directly at variance with his inclination. From this time he devoted himself wholly to the study of his favourite science; and in 1727 he established his reputation by publishing a Theory of the Aberration of the Fixed Stars, which is allowed to be one of the most useful and ingenious discoveries of modern astronomy. Three years afterwards he was appointed lecturer in astronomy and physics in the university of Oxford. In the course of his observations, he discovered that the inclination of the earth's axis upon the plane of the ecliptic was not always the same, but that it varied backwards and forwards some seconds, and that the period of these variations was nine years. This period seemed altogether unaccountable, as it could not be supposed to have anything in common with the revolution of the earth, which

is performed in one year. Bradley, however, discovered

Brady.

Bradninch the cause of this phenomenon in the Newtonian system of attraction, and published his discovery in 1737; so that in the space of about ten years he communicated to the world two of the finest discoveries in modern astronomy, which will for ever form an epoch in the history of that science.

In 1742 he had the honour of succeeding Dr Halley as astronomer-royal. That great man, now worn out with age and infirmities, had intended to resign in favour of Bradley; but while occupied with this friendly project, he died. As soon as Bradley's appointment became known, the university of Oxford created him doctor of divinity. Bradley was now in his proper element, and pursued his observations with unwearied diligence. In 1748 he availed himself of the annual visit made by the Royal Society to the observatory, to represent the necessity of repairing the old instruments and purchasing new ones; and in consequence, a grant of L.1000 was made by the king for that This sum enabled the astronomer-royal to furnish the observatory with as complete a collection of astronomical instruments as this most skilful and diligent obsever could then procure.

In 1751 Bradley received an offer of the vacant vicarage of Greenwich, a very considerable living, and conveniently situated for the performance of its duties; but this offer he declined on conscientious grounds. The king, on hearing of the refusal, granted him a pension of L.250 a-year, in consideration of his great abilities and knowledge in astronomy and other branches of the mathematics, which had proved so advantageous to the commerce and navigation of Great Britain, as is particularly mentioned in the grant, dated the 15th of February 1752. About the same time he was admitted into the council of the Royal Society, and in 1748 he was elected a member of the Royal Academy of Berlin. In 1752 he was made a member of the Imperial Academy at Petersburg; and in 1757, of that instituted at Bologna.

Till within two years of his death, Bradley continued to be indefatigable in his observations, and every honour he received became an excitement to fresh exertion; and when at last his strength gave way, the vigour of his intellect suffered no abatement. He died, after a painful illness, on the 13th of July 1762. He had married in 1744 Susannah Peach, a lady of Gloucestershire, by whom he had one daughter.

Dr Bradley possessed an amiable disposition and great equanimity of temper. Though a good and clear speaker, he was remarkably silent, never speaking except when he thought he could communicate some useful knowledge. He was not more inclined to write than to speak, and published very little, having had a diffident aversion to attract public notice. Two volumes of his observations were published at Oxford in 1798 and 1805.

BRADNINCH, or BRAINES, a decayed borough in the hundred of Hayridge, Devonshire, 9 miles N.N.E. of Exeter. It is pleasantly situated on an eminence surrounded by higher hills, except on the south, and consists for the most part of neat thatched cottages. It has a fine old church, guildhall, gaol, court-house, and national school; two papermills, and a small woollen factory. Pop. (1851) 1834. It is governed by a mayor, 12 masters, and 24 burgesses, and before the time of Henry VII. returned two members to parliament.

BRADS, a kind of nails made without spreading heads. They are distinguished as joiners'-brads, flooring-brads, battan-brads, bill-brads, quarter-heads, &c.; and are used for floors and other work in which it is required that the nails be sunk entirely in the wood.

BRADSHAW, HENRY, an English poet, born at Chester about the middle of the fifteenth century. Early displaying a taste for religion and literature, he was received while a boy into the Benedictine monastery of St Werberg

in that city; and he was afterwards sent to Gloucester (now Bradshaw Worcester) College, Oxford. After studying there for a time with the novices of his order, he returned to his convent, where, in the latter part of his life, he applied himself chiefly to the study of history. He died in 1513. His poetry in some respects is not inferior to that of any of his contemporaries. His works are, 1. De antiquitate et magnificentia Urbis Cestriæ; 2. Chronicon; 3. The Life of the glorious virgin St Werberg, printed at London, 1521, 4to, in verse, and now extremely rare. The life of St Werberg forms only part of this work, which contains also a description of the kingdom of Mercia, a life of St Etheldred, a life of St Sexburg, the foundation and history of Chester, and the chronicles of some kings.

Bradshaw, John, president of the court which condemned Charles I., was descended of an ancient Lancashire family, but the branch to which he belonged was seated either in Cheshire or Derbyshire. Being appointed speaker or president of the parliament under Cromwell, a guard was assigned him for the safety of his person, together with apartments in Westminster, a sum of L.5000 sterling, and considerable territorial domains. But he was not destined long to enjoy the recompense of the judicial service he had rendered; for, according to the pamphlets of the time preserved in the British Museum, he withdrew from parliament, and died in obscurity in 1659. At the Restoration his body, with those of Cromwell and Ireton, was disinterred, suspended on the gallows at Tyburn, and burned. Yet several collectors of anecdotes have circulated an idle story that Bradshaw passed into the colonies (Barbadoes or Jamaica) under a feigned name, and signalized himself in various contests with the native tribes. (Gentleman's Ma-

gazine, vol. liv. p. 834.) Bradshaw, William, an eminent English Puritan, born in 1571 at Market-Bosworth, in Leicestershire. His chief claim to notice as an author rests on a small treatise, entitled English Puritanism, published in 1605, which is valuable as a record of the main opinions of the most rigid Puritans of his time. He died in 1618.

BRADWARDIN, THOMAS, archbishop of Canterbury, surnamed the Profound Doctor, was born at Hartfield in Sussex towards the close of the 13th century. He was educated at Merton College, Oxford, where he took the degree of doctor of divinity, and acquired the reputation of a profound scholar, a skilful mathematician, and an able divine. He was afterwards raised to the high offices of chancellor of the university and professor of divinity. From being chancellor of the diocese of London, he became chaplain and confessor to Edward III., whom he attended during his wars in France, assisting that victorious prince with his advice, animating the troops, and aiding them with his prayers. After his return from the war he was made prebendary of Lincoln, and subsequently archbishop of Canterbury. He died of the plague, at Lambeth, in the year 1349, forty days after his consecration. Chaucer, in his Nun's Priest's Tale, ranks Bradwardin with St Augustine. His great work is a treatise against the Pelagians, entitled De causa Dei, printed at London, 1618, folio, by Sir Henry Savile. He wrote also De Geometria speculativa, Paris, 1495, 1512, 1530; De Arithmetica practica, Paris, 1502, 1512; De Proportionibus, Paris, 1495, Venice, 1505, folio; De Quadratura Circuli, Paris, 1495, folio.

BRADY, ROBERT, a physician and historian of the seventeenth century, was born in Norfolkshire, and studied at Caius College, Cambridge, where he took his degree of M.D. in 1660. About 1670 he was appointed keeper of the records in the Tower; and was afterwards made regius professor of physic in the university of Cambridge. He wrote a letter to Sydenham on the influence of air, which was published at the head of that learned physician's Epistolæ Responsoriæ. His principal work is A complete HisBrady Braga.

tory of England from the first entrance of the Romans unto the end of the reign of King Richard II., with an Introduction to the old English History, &c., in three vols. fol., 1685 -1700. In his Introduction he maintains, that the representatives of the Commons in parliament, knights, citizens, and burgesses, were not introduced until the forty-ninth of Henry III.; that William of Normandy made an absolute conquest of the nation; and that the succession to the crowu of England is hereditary and not elective; -- principles which were afterwards adopted by Hume as the basis of his History. His other productions were, An Answer to Mr Petyt's Book on Parliaments, London, 1681, 8vo; and An Historical Treatise of Cities and Burghs, 1690, folio, both contained in the volumes of his history. Brady sat in parliament for the university of Cambridge in 1681; and again in 1685, under James II., to whom he afterwards became physician in ordinary. He died in August 1700.

BRADY, Nicholas, D.D., whose name is familiar as the translator, in conjunction with Tate, of a new metrical version of the Psalms, was born at Bandon, in the county of Cork, in October 1659. He received his early education at Westminster School, and then studied at Christ Church, Oxford; but he graduated at Trinity College, Dublin. He was in due time made a prebend of Cork. He was a zealous promoter of the Revolution, and suffered in consequence. the troubles broke out in Ireland in 1690, Brady by his influence thrice prevented the burning of the town of Bandon, after James II. had given orders for its destruction; and the same year he was employed by the people of Bandon to lay their grievances before the English parliament. He soon afterwards settled in London, where he obtained various preferments. At the time of his death, in 1726, he held the livings of Clapham and Richmond. Besides his version of the Psalms, which was licensed in 1696, he translated Virgil's Æneid, and wrote a tragedy entitled The Rape, or the Innocent Imposture, both very indifferent performances. His prose works consist of Sermons.

BRAEMAR, a district of Scotland, in the county of Aberdeen. See Aberdeenshire.

BRAG, a game at cards, played by any number of persons; the dealer giving three cards to each person at one time, and turning up the last card all round. This being done, each player puts down three stakes, one for each card. The first stake is won by the best card turned up in the deal, beginning with the ace, and so on. When cards of the same value are turned up to two or more, the eldest hand gains; but the ace of diamonds wins, to whatever hand it be turned up. The second stake is won by what is called the brag, which consists in one of the players challenging the rest to turn up cards equal to his. A pair of aces is the best brag, a pair of kings the next, and so on; and a pair of any sort wins the stake from the most valuable single card. In this consists the great diversion of the game; for by plausible management, a pair of fives, trois, or even deuces, in the hands of a clever player, may outbrag a much higher pair, and even some pairs royal. The knave of clubs is here a principal favourite, making a pair with any other card in hand, and with any other two cards a pair royal. The third stake is won by the person who first makes up the cards in his hand one and thirty; each court card going for ten, and drawing from the pack, as usual in this game.

BRAGA (the ancient Augusta Bracara), the capital of the province of Entre Douro-e-Minho, in Portugal, is situated on an elevated plain near the river Savado. It is fortified, and defended by a citadel. The streets are irregular and ill paved, and the houses large, but of an antique fashion. It has an archbishop, and, besides the cathedral, numerous churches and monasteries, an archiepiscopal palace, and several hospitals. It has many fountains, and some Roman remains. Its chief manufactures are fire-arms, cutlery,

jewellery, and hats. Pop. 16,000. Long. 8. 16. W. Lat. 41. Bragança 43. N.

BRAGANÇA, a town of Portugal, province of Tras-os-Montes, on the Ferrenza, 26 miles N.W. of Miranda. It is partially fortified, is the seat of a bishopric, and has a citadel, a college, and some manufactures of silk and velvet. Pop. 5000. The reigning houses of Portugal and Brazil are descendants of the old Dukes of Bragança.

BRAHE, Tycho, an illustrious astronomer, descended of a noble family, originally of Sweden but settled in Denmark, was born on the 14th December 1546, at Knudstorp, in the county of Schonen. He learned Latin at the age of seven, and studied five years under private tutors. On the death of his father his uncle sent him, in April 1559, to study philosophy and rhetoric at Copenhagen. The great eclipse of the sun, on the 21st of August 1560, happening at the precise time foretold by astronomers, he began to look upon astronomy as something divine; and having purchased the Ephemerides of Stadius, he gained some notion of the theory of the planets. In 1562 he was sent by his uncle to Leipzig to study law; but astronomy wholly engrossed his thoughts, and he employed all his pocket-money in purchasing books on that science. Having procured a small celestial globe, he used to wait till his tutor went to bed, in order to examine the constellations and learn their names; and when the sky was clear, he spent whole nights in viewing the stars. In 1565, his choleric disposition involved him in a duel with a Danish nobleman, in which he had the misfortune to lose part of his nose; yet this defect he so skilfully supplied by means of gold, silver, and wax, that it was scarcely perceptible. It was about this time that he began to apply to chemistry, proposing nothing less than the discovery of the philosopher's stone. In 1571 he returned to Denmark, and was favoured by his maternal uncle Steno Belle with a convenient place at his castle of Herritzvad, near Knudstorp, for making his observations, and building a laboratory. But his marrying a peasant girl occasioned a violent quarrel between him and his relations, and the king was obliged to interpose in order to reconcile them. In 1574, byroyal command, he read lectures upon the theory of comets at Copenhagen; and the year following he began his travels through Germany, and proceeded as far as Venice. He then resolved to remove his family, and settle at Basle; but Frederick II., unwilling that Denmark should lose the honour of his residence, bestowed upon him for life the island of Huen in the Sound, to erect an observatory and laboratory there, and conferred on him a pension of two thousand crowns out of the treasury, a fee in Norway, and the canonry of Roschild, which brought him in a thousand more. The first stone of the observatory was laid on the 8th of August 1576. James VI. of Scotland, afterwards James I. of England, on his visit to Denmark to marry the Princess Anne, went to see Tycho Brahe in his retirement at Uranienburg, made him several presents, and wrote a copy of verses in his praise. But soon after the death of King Frederick he was deprived of his pension, fee, and canonry. Finding himself incapable of bearing the expenses of his observatory, he went to Copenhagen, whither he carried some of his instruments, and continued his astronomical observations in that city, till by the order of Christian IV., he was obliged to discontinue them. He then removed his family to Rostock, and afterwards to Holstein, in order to solicit Henry Ranzou to introduce him to the emperor; and accordingly he was received by Rodolph II. at Prague with the most gratifying marks of respect. That prince gave him a magnificent, house till he could procure. for him one better fitted for astronomical observations; assigned him a pension of three thousand crowns; and promised, upon the first opportunity, a fee for him and his descendants. But he did not long enjoy his good fortune; for, on the 24th of October 1601, he died of a strangury, in the

Brahmins.

Brahilow fifty-fifth year of his age. He was interred in a very magnificent manner in the principal church at Prague, where a noble monument was erected to his memory.

Tycho Brahe, though an accurate observer, and possessed of a powerful understanding, refused to admit the truth of the Copernican system, choosing rather to frame a complicated system of his own, but which, indeed, was adopted by few. The Tychonian system, as it is called, is essentially that of Ptolemv. with certain modifications. This great that of Ptolemy, with certain modifications. astronomer was extremely credulous with regard to judicial astrology and presages. If on leaving his house, he met an old woman or a hare upon the road in a journey, he would immediately turn back, persuaded that it was a bad omen. At Uranienburg, he had in his house a madman, whom he placed at his feet at table, and fed with his own hands, superstitiously regarding as prophetic whatever he uttered. Tycho was a man of very violent temper, easily excited to resentment, and though fond of rallying others, was highly provoked if the same liberty were taken with himself. His life has been written by Gassendi. His principal works are, 1. Progymnasmata Astronomica, Uranienburg, 1588 and 1589, 2 vols. 4to; 2. De Mundi Ætherei recentioribus phænomenis, 1588, 4to; 3. Epistolarum Astronomicarum libri duo, Frankfort, 1610, 4to; 4. Calendarium Naturale Magicum, 1582; 5. Oratio de Disciplinis Mathematicis, Copenhagen, 1610, 8vo. His observations were collected by his disciples, and published in 1666 in Historiæ Cælestis xx. libris.

It was the friendship of Tycho which formed Kepler, and directed him in the career of astronomy. The numerous observations of Tycho, of which Kepler found himself the depositary after the death of his master, doubtless contributed greatly to the discovery of those great laws of the system of the world which are known as Kepler's laws, and which, combined with the theory of central forces discovered by Huygens, conducted Newton to the grandest discovery which has ever been made in the sciences, namely, that of

universal gravitation.

BRAHILOW, BRAILOFF or IBRAILA, a town of European Turkey, in the province of Wallachia, on the left bank of the Danube, 100 miles N.E. of Bucharest, and about the same distance from the Black Sea. As the channel of the river is deep between Brahilow and the sea, vessels of considerable burthen can sail up to the town. Its harbour, protected by a small island from the ice that drifts down the river in large quantities in winter, affords complete security to the shipping. In 1770 the town was taken by the Russians, and almost razed to the ground, but it has been rebuilt, and many streets and edifices added, which its increasing trade and importance rendered indispensable. Its trade, which consists principally in the produce of the surrounding country, such as wheat, barley, maize, hides, tallow, timber, and tobacco, has of late years increased with surprising rapidity. The exports of grain, from 200,000 qrs. in 1838. had increased in 1849 to more than a million qrs., of the value of about £450,000. The quality of the grain used to be considerably impaired by the damp of the pits in which it was kept, but of late years spacious warehouses have been erected, and the quality of the grain has greatly improved. The trade is managed chiefly by Greeks, but many English and other merchants are now engaged in it. Pop. about 8000.

BRAHMA, the supreme god of the Indians. In Hun- Brahma dustani, the word is a neuter noun, derived by grammamans from the verb brih to grow, and the suffix man, and thus means that which grows, or the Supreme Being regarded under the aspect of development, and revealed by the creation of worlds. The word is used, however, in a secondary sense also, and means the Supreme Absolute Spirit, not regarded as a creative force, but shut up in himself, without external manifestations of any kind.

BRAHMAPOOTRA, or Burrampooter, one of the largest rivers in India, deriving its origin from the unexplored region at the eastern termination of the Himalaya mountains, in Lat. 28. 30. Long. 97. 20. Commencing with a westerly course it enters the province of Assam, and shortly after receives the tributary waters of the Dihong, a river of greater magnitude at the point of junction than itself; and which, rising under the name of the Sanpoo in the vicinity of the sources of the Sutlej and the Indus, winds eastward through the territory of Thibet for a thousand miles before its confluence with the Brahmapootra. In Long. 94. 30. the united streams divide into two great branches

which inclose an island of sixty miles in length.

Continuing its course westward it enters Bengal near to the town of Goalpara, after which it makes a circuit round the Garrow Mountains; and then altering its course to the south it is joined by the Megna in Lat. 24° in the district of Dacca. From this point the river loses its previous appellation of the Brahmapootra and assumes that of the Megna, the waters of which disembogue into the Bay of Bengal through three separate branches, one of these being the channel of the Ganges, with which the Megna communicates at the distance of about 40 miles from the sea. This great river, including its windings, has a course of about 930 miles, a length which would be doubled if the continuous streams of its remotest feeder, the Dihong, be included. Until 1765 the Brahmapootra was unknown in Europe as a great river, and Major Rennell, on exploring it, was surprised to find it larger than the Ganges. During a course of 400 miles through Bengal, the Brahmapootra resembles the Ganges in all respects, except that during the last 60 miles before its junction with that river, it forms a stream which is regularly from four to five miles wide, and but for its freshness might be considered an arm of the sea. The junction of the two mighty streams of the Brahmapootra and the Ganges produces an immense body of fresh water, such as is only exceeded by some of the great rivers in Africa which lie entirely within the limits of the tropical rains, or the Amazons and Orinoco in South America. The bore, which is known to be occasioned by the sudden influence of the tide into a river or narrow strait, prevails in all the passages between the islands and sands situated in the gulf formed by the confluence of the Brahmapootra and the Ganges, in a greater degree than in other (D. B-N.) (E. T.)

BRAHMINS, BRAMINS, BRAHMANS, OF BRACHMANS, called Bpaxuavai by the Greek writers, the name employed to designate that body or order of priests who have always been the sole guardians, preceptors, and ministers of the Hindu religion. It is formed, by a slight modification, from that of Brahma, which is itself a derivative from Brahm, the Supreme Being, indicating the first of the

¹ This order is of extreme antiquity, and they and their followers are universally acknowledged as a tribe sprung from the Caucasian variety of the human species. According to Major-General Briggs, in a memoir published in 1851, their sacred books or *Vedas* represent them as invading India from the N.W., i.e., through Afghanistan and the Punjaub at a very early period, where they seem to have made more considerable progress in literature, philosophy, mathematics, and medicine, than their contemporaries in other regions of the world. It is asserted that their Vedas date from fourteen centuries before our era; and it is alleged that their codes of criminal and civil law extend as far back as twenty-seven centuries from the present time. The progress of the Hindus southward was slow. For long they seem not to have penetrated farther south than Lat. 22° N.; and it was as late as in the ninth and tenth centuries of our era, that they encountered a kindred tribe, the followers of Buddah, who appear to have then possessed Southern India for a long period on the banks of the Kisma and Godavery. The Buddists were gradually overpowered, but were dominant in Ceylon, and still powerful at Bombay, in the fourteenth century.—En.

Brahmins, three divine hypostases of the Hindu mythology, the in number, for each of which there is a separate class or Brahmins. creator of the world under Brahm, and the author of the sacred books called Vedas.

The Brahmins constitute the first or highest of the four tchadi or castes into which the Hindu nation continues to be divided, as it has been from a very remote antiquity. The origin of this singular division or classification, which prevailed in ancient Egypt as it still does in the peninsula of India, and which was based upon nearly the same principles in both, is hid in the obscurity of ages. Each caste has its peculiar privileges, duties, and laws, all of which are incommunicable and unalienable. The more honourable the caste is, the more numerous are the restrictions to which its members are subjected, and the higher the prerogatives they enjoy. The fourth caste has the fewest observances to follow, but it has also the least portion of respect, and is the most limited in its rights and privileges. Every individual remains invariably in the caste in which he is born; practises its duties as prescribed in the laws relative thereto; and is precluded from ever aspiring to a higher, whatever may be his genius, his virtue, his patriotism, or his courage. The law which determines every man's position in society is immutable; and dreadful are the penalties which await him who ventures to dispense with even the most absurd rules laid down in it. To this point of honour the Hindu patiently sacrifices not only health, but life itself; degradation and infamy await him who transgresses its dictates; yet, although the code of which this constitutes part has been in force for a long series of ages, the people have never (perhaps for this very reason) thought of moderating its rigour or mitigating its oppression.

The leading castes among the Hindus are, as we have already observed, four. These are, first, the Brahmins; secondly, the Kshatriyas, or soldiers, including the princes and sovereigns, and hence sometimes called the caste of Rajahs or Rajeputras; thirdly, the Vaisyas, consisting of agriculturists and shepherds; and, fourthly, the Sudras or labourers. It is with the first of these, however, namely the Brahmins, that we are at present exclusively concerned. This is the sacred or sacerdotal caste, the members of which have maintained an authority more exalted, comprehensive, and absolute, than the priests of any other people, excepting perhaps those of ancient Egypt before the Persian invasion under Cambyses. According to the received Brahminical tradition, that priesthood originally proceeded from the mouth of Brahma, which is the seat of wisdom, and thus, by the mere fact of their genesis, became invested with an undoubted superiority over the other castes, which sprung from inferior organs or members of the hypostatical creator; as the Kshatriyas from his heart, the Vaisyas from his belly, and the Sudras from his feet. Of the Brahmins there are seven subdivisions, which derive their origin from the seven Rishis or Penitents, the most sacred personages acknowledged by the Hin-The Rishis are of high antiquity, being mentioned in the Vedas; and they are believed to have occasionally exercised a salutary superintendence over the gods themselves, visiting with their holy displeasure such of the divine impersonations as had been guilty of any irregularity. Their residence was fixed in the remote and elevated regions of, the north; and hence the Brahmins of the north are esteemed as the noblest, from their proximity to the great fountain. The Gymnosophists, or Brahmins of antiquity, lived much more secluded than those of modern times, who mingle to a considerable extent in secular concerns. But the latter have made almost no change in their rules of abstinence, their ablutions, and multiplied ceremonies. Their great prerogative consists in being the sole depositaries and expounders of the Vedas or sacred books, four first commences at the age of from seven to nine, when

branch of the Brahmins. This prerogative they guard 's with the most jealous care, affirming, that if a Sudra or other profane person were to attempt to read even the title of these books, his head would instantly cleave asunder; and a Brahmin bold enough to exhibit the sacred volumes to profane eyes would incur the penalty of irretrievable expulsion from his caste. Yet, with much judgment, they make an exception as to the miracle in favour of Europeans; nor has it been found expedient to enforce the law of caste against such Brahmins as may have indulged them with a perusal or even with copies of the Vedas.

The great body of the Brahmins profess to pay equal veneration to the three hypostases of the godhead, Brahma, Vishnu, and Siva. But some attach themselves exclusively to one of these impersonations; while others, admitting the divine emanation of three, exhibit only a preference in their homage, founded on certain fanciful distinctions. Thus Vishnu and Siva, though nominally co-ordinate with Brahma, have long been objects of partiality with individuals who, in virtue of such preference, are formed into sects, distinguished by the name of the hypostasis to which their chief homage is paid. The worshippers of Vishnu are denominated Namadhari, from bearing in their foreheads the mark called Nama, consisting of three perpendicular lines, crossed at the lower extremity by a horizontal one, so as to form a sort of trident; and their dress is of a deep orange colour. The devotees of Siva are denominated Lingamhari, from wearing the Lingam stuck in their hair, or attached to the arm in a tube of gold or silver. The former are notorious for intemperance, and on that account disliked by the people; the latter, for the most part, observe great moderation both in eating and drinking. The devotees of Vishnu account as sacred the monkey, the garuda, and the cobra capella; and any of their number who inadvertently kills one of these animals is obliged to expiate his supposed crime by a farcical sacrifice, in which it is pretended that a human victim is immolated and brought to life again. The mummery of this mock expiation is abundantly ridiculous. A little blood is drawn from a superficial wound in the thigh, inflicted with a knife; the victim is then supposed to be slain, and remains motionless until the farce of resuscitation is performed, when he of course comes to life again. This is performed with immense ceremony, in the presence of a great concourse of spectators, who are commonly feasted on the fine levied from the culprit; and a similar punishment is sometimes inflicted for other offences. The worshippers of Vishnu and Siva, though separated by a very thin wall of partition, are continually at variance, each sect not only striving to exalt their own divinity, but to revile that of their adversaries. The former consider the wearing of the Lingam as the most heinous of all sins; the latter, on the other hand, maintain that all who bear the Nama will, after death, be tormented in hell with a three-pronged fork, resembling that tridental mark. But these sectarian notions are less prevalent among the Brahmins than the other castes. Brahmins of the Vishnu faith are only to be found in the provinces situated to the south of the Krishna, and they are regarded with contempt by their more tolerant brethren, who, in consequence, refuse to admit them to their tables or to their ceremonies, and anxiously exclude them from any public employments which happen to be at their disposal. The sects of the Nama and the Lingam are further split into subdivisions, which dispute warmly on the subjects of their differences, but are ever ready to unite when the general interests of the order are concerned.

There are four stages in the life of a Brahmin. The

efficacious forms of prayer called the Mantras; and in acquiring other knowledge. It is his duty to abstain from the use of betel, to put no ornaments in his hair, to bathe daily, and to offer the sacrifice called Homam twice a day; but subjects so young seldom observe the rules strictly. A certain proficiency, indeed, is enjoined in committing to memory the sacred books; but neither in this nor in the acquisitions which are deemed scientific is there much emulation. They are not slack, however, in learning to understand the privileges belonging to their caste, which are great and various. One of these is a right to ask alms, which they do not in the style of mendicants, but in that of confident yet not insolent claimants; another is, an exemption from taxes of all kinds, whether general or local; and a third consists in an immunity from capital, and generally from corporal punishment, however heinous the crimes they may commit, imprisonment being the only penalty to which they are liable. At this stage also they learn the different points of bodily purity which, as good Brahmins, it is necessary for them to observe through life. These are so numerous as to be excessively burdensome, and to impose on them the duty of constant and jealous vigilance. Not only are they defiled by touching a dead body, but even by attending a funeral. Childbirth and constitutional changes render females impure; and certain ablutions and forms of prayer are necessary to remove the stain. An earthen vessel, if it has been used by a profane person, or applied to certain specified purposes, becomes so polluted that it cannot be used again, and must be broken; but metallic vessels may be purified by washing. Leather and all kinds of skins, except those of the tiger and antelope, are held to be excessively impure; and the boots and gloves of Europeans are to them the most disagreeable of all articles of dress. Brahmins, in walking or sitting, must take care they do not touch a bone, a broken pot, a rag, or a leaf from which any one has eaten; in drinking, they must pour the liquid from above, without touching the vessel with their lips; and they are forbidden to touch the greater part of animals, particularly the dog, which is accounted the most polluting. The water which they drink must be carefully drawn, though never by a Sudra; and if two Brahmins draw water together, their pitchers must not come in contact, otherwise one or both must be broken. Animal food of all kinds is strictly prohibited; and among the Lingam branch of the order the prohibition is most rigidly observed, notwithstanding which this class or sect has always been remarkable for great slovenliness in their external habits. The Brahmins are also taught to entertain a horror of spiritual defilement, resulting from perversity of will, or the actual commission of sin; and although the different modes in which it is contracted are but obscurely indicated, the rules for purification by means of ablutions, penances, and ceremonies, are very fully and distinctly laid down.

The second stage of a Brahmin's life is the state of Grihastha, which takes place when he is married, and has children; both these circumstances being essential to its constitution. Marriage is an important object to a Brahmin, inasmuch as it insures him consideration and respectability in society. Hence, when he becomes a widower, he falls from his station, and is consequently under a moral necessity of re-entering the married state. But the case is quite different with widowed females, who are not

Brahmins. he is invested with the triple cord, which is suspended ever, probably in imitation of the ancient Rishis, lead lives Brahmins. from the left shoulder, and forms the badge of his order. of celibacy; and the acting priests, called Gurus, also live The youth thus initiated is denominated Brahmachari. At in a state of single blessedness, although their morality this stage he is occupied in learning to read and write; in this particular is sufficiently relaxed. When a Brahin committing to memory portions of the Vedas, and the min, therefore, takes his wife home and has children by her, he enters his second state, or that of Grihastha. His daily duties and ceremonies now become more multiplied and imperative; and every act of his life must be performed according to certain rules, some of them sufficiently repugnant to European notions of propriety. These observances, which from their number and incessant recurrence would seem burdensome and oppressive, become so habitual from daily practice that they are not felt as galling or irksome. On the contrary, the Brahmins perform all of them cheerfully, and no innovation is ever proposed. Some Hindu writers, indeed, have turned them into ridicule, and joked at the expense of a ritual which they nevertheless continued in practice to observe. But, from all that we can learn, the authors who have indulged in this license were never Brahmins, but generally Sudras, or men of the lowest caste, who had been contaminated by association with Europeans. Vemana, Agastya, Patanatupulai, and Tiruvaluven, a Pariah, the principal scoffers, answer to this description; they are all modern, and either Sudras or men of no caste whatever. If any ancient authors wrote in the same strain, their names and their works have equally perished. At the same time, although speculative scepticism be but rarely avowed, practical transgressions are secretly indulged in, especially in large towns, where concealment is easy and temptation strong.

Nor is this all. Many Brahmins habitually engage in transactions and employments which appear altogether at variance with their professions and pretensions. They are commonly the political functionaries or agents of the native princes, and of the Mahommedan governments, which find it convenient to employ these hereditary ministers of religion, from the influence they possess over the minds of the people. Some of them, particularly in Gujerat, cmbark in commercial speculations, and become merchants, bankers, or general agents. Others, again, carry messages between distant places, or are sent as vakeels on difficult and important missions; the veneration in which they are universally held securing them from molestation in the discharge of such tasks. A third class act as coolies or porters, in which character they alone are exempt from the demands of the tax-gatherer. Many of them enter the Company's native army, and often rise to the rank of subadhar. In a word, they are as much alive to selfish considerations and interests as any other tribe or caste, and ready, on all occasions, to avail themselves to the uttermost of the privileges and immunities belonging to their order. Their rapacity, in fact, is only exceeded by their cunning; nor is there to be found in any country a set of more artful impostors. The Hindus are all expert in disguising the truth; but the Brahmins, in this respect, possess an unquestioned superiority. They are supple, insinuating, false; acute in discerning, and skilful in taking advantage of the foibles of others; naturally vindictive and proud, yet, from habit and cunning, patient and submissive; evincing on all occasions the most perfect self-command, and ever ready to profit by the indiscretion, weakness, or simplicity of those with whom they may have to do. One of their prime resources is flattery, which they lavish with unbounded profusion on any person whom they wish to cozen or hope to conciliate; experience having convinced them, that even those who pretend to repudiate their adulation nevertheless lay a portion, at least, of the grateful unction to their souls. In matters of religious opinion they are upon the whole tolerant; they almost never anathematize permitted to marry a second time. The Sunnyassis, how- Moslemins, Christians, and others of different creeds; nor

Brahmins do they seem to be at all actuated by the fierce spirit of for the severe discipline of the order; but in the end the Brahmins the objects of their own worship; for, undoubtedly, they sometimes treat the latter with an indifference bordering on contempt, and in their adorations are influenced by their secular interests rather than by the spirit of devotion, flattering those divinities whose functions they connect with their worldly affairs, and giving themselves no concern about the others.

The distance at which they keep themselves from Europeans, and the unwillingness they evince to admit the latter to their temples or their ceremonies, may seem inconsistent with what has just been advanced. But their conduct in this respect arises solely from the uncleanness which they attach to our habits; and were Europeans to conform a little more to their manners and practical prejudices, there can be no doubt that the consequence would be a closer intimacy and unbounded toleration. This was fully experienced by the Abbé Dubois, who having carefully studied the manners of the Hindus, and uniformly treated their habits with respect and tenderness, was often invited by the Brahmins of his acquaintance to enter their temples and join in their ceremonies. Among the sacerdotal order of India it is a prevalent sentiment that different religions are formed for different nations, and that each serves every necessary purpose to the souls of its believers and professors. But in their attachment to their civil institutions the Brahmins are less liberal and conciliating, considering every thing different from these or opposed to them as the product of absolute barbarism. The Moors they hate for their arrogance, and despise for their ignorance of some branches of mathematical science known to themselves, such as those connected with the construction and explanation of the almanack. In the European masters of India, they admire their humanity in war, the moderation and impartiality of their government, the general uprightness of their conduct in the intercourse of life, and the benevolent generosity of their dispositions; but these favourable impressions are apt to be forgotten when they think of the grossness and hatefulness of their prevailing habits, such as eating animal food, and admitting the detested Pariahs into their domestic service. Such things are pre-eminently odious to Hindus, and both, we think, might have easily been avoided. No extraordinary effort of self-denial would have been necessary to enable Europeans to abstain from the use of beef, which is an insipid food in India; and, with regard to the Pariahs, although it would undoubtedly be wrong to countenance the Brahmins in their barbarous treatment of the inferior castes, and of those who are considered as of no caste, yet regulations might have been adopted by which men of high caste would have been spared the gross insults they are at present exposed to, and every humane purpose at the same time attained.

The third state of a Brahmin is denominated Vanaprastha, or that of inhabitants of the desert. The order of Brahminical anchorites prevailed at a former period, but it is now scarcely to be found, and appears to be very nearly, if not altogether, extinct. The members of it were usually styled Rishis, or Penitents. They were honoured by kings, and respected by the gods, who, on account of the odour of their sanctity, seem to have considered them as in some degree their superiors. They performed peculiar sacrifices and religious observances. Their pious acts and intentions were often thwarted by giants, and even by gods, who seem to have had no relish sons; the Panduris, who carry about small figures of the

proselytism and persecution. But this forbearance may Penitents always prevailed, and sometimes took the gods perhaps be the consequence, not of any virtue in the roundly to task for their misdeeds. They were the depo-Brahmins, but of the low estimation in which they hold sitaries of the more sublime doctrines of theology, and practised magical incantations.

The fourth state of a Brahmin is called Sunnyassi, and is reckoned so pre-eminently holy that, in a single generation, it imparts a greater stock of merit than could be accumulated during ten thousand in any other sphere of life. As a natural consequence, when a Sunnyassi dies, he is believed to pass at once into the region of Brahma or Vishnu, exempt from the penalty of being re-born on earth, or animating in succession different bodies, conformably to the metempsychosis of the Hindu mythology. In preparation for this state, a Brahmin performs all the rites of the Vanaprastha, and in addition renounces every worldly connection, takes up the profession of mendicity, and lives solely by alms. He must previously, however, have devoted several years to the married and paternal state, and thus discharged the debt which he owed to his forefathers. When duly qualified and disposed for entering the holy state of Sunnyassi, he is installed as such with many Mantras and other ceremonies. His duties now increase in number and severity. He must every morning rub his whole body over with ashes, restrict himself to one meal a day, give up the use of betel, avoid looking at women, shave his beard and head every month, and wear wooden clogs on his feet; in travelling, he must carry his seven-knotted bamboo staff in the one hand, his gourd in the other, and the antelope skin under his arm, in other words, display the three badges of his order; and he must erect a hermitage on the bank of a river or a lake. Contemplation, and a supposed communion with the Deity, amounting in its highest form to a participation of the divine essence, constitute the ulterior duties of this class of devotees. Need we wonder that, being thus privileged to indulge in all manner of extravagances, and to give full swing to an excited imagination, their practices should be in the highest degree preposterous, and their fantasies equally wild and ridiculous? In fact, the tricks which they perform are endless. The highest act of merit among them is "to subdue all sensation, and retain the breath with such determined perseverance, that the soul, quitting the body, bursts through the crown of the head, and flies to re-unite itself with the Great Being, or Para-Brahma." Accordingly, one of their fantastical exercises consists in suppressing their breath as long as possible, till they almost swoon away, and bring on most profuse perspiration. Another consists in putting themselves in the most irksome and ridiculous postures, and remaining so for a considerable length of time, indeed till exhaustion or decrepitude ensue. To stand on one leg till it swells and ulcerates; to stand on the head till the brain becomes disordered, and delirium ensues; to keep one arm extended aloft in the air till the muscles become rigid, and the power of withdrawing it is lost for ever; such are among the most approved practices of the Sunnyassis. But still the most extravagant and fatal efforts of these extraordinary devotees seem to have been confined to former times. We may add, that the Sunnyassis are not, like the Vanaprasthas, burned when they die, but interred. the case with the Lingamhari, or worshippers of Siva; but a Sunnyassi, even although he had, during life, attached himself to the worship of Vishnu, is interred when dead, and the ceremony is both pompous and expensive.

From the classes of Vanaprastha and Sunnyassi have practised self-denial according to certain rigid rules, and sprung numerous sects of fanatics, such as the Djogis, who seek to propitiate the Deity by mutilating their bodies, or braving the force of fire and the inclemency of the sea-

and the Vairagis, who form a kind of mixed order of monks and nuns, consecrated to the god Krishna and his mistress Rada, whose history they celebrate in songs, accompanied with the tinkling of cymbals. It is also said that some of the Brahmins, under the denominations of Pashandia and Sarwagina, maintain libertine and atheistical opinions; and it is probable that the number of those who secretly cherish such sentiments is much greater than that of the class or sect which openly avows them. Superstition, when sustained neither by fanaticism nor enthusiasm, is the natural parent of that infidelity by which it is ultimately undermined.

From what has been stated in the course of this exposition, some idea may be formed of the general character of the sacerdotal caste in India. According to the best authorities on the subject, the number of Brahmins who are respectable for their knowledge and their virtue is exceedingly small; whilst the great majority of these hereditary priests is completely devoted to ambition, intrigue, and voluptuousness, and disgraced by an avarice, a meanness, and a cruelty, which inspire strangers with no sentiments towards them but those of contempt and aversion. The charity which they place so high in the scale of duties and virtues, being equally confined by the law of caste, and the operation of that intense selfishness by which the whole tribe is characterised, has no human beings except Brahmins for its objects. Towards the other castes they cherish no feeling of humanity, and cautiously abstain from any reciprocation of kindness; they exact every thing in virtue of their rank, functions, and pretended sanctity, but take care to give nothing in return. Instead of the retired and contemplative life which appears to have been observed by the order in ancient times, and to which they still profess to devote themselves, they are immersed, as we have already seen, in pursuits the most foreign to and inconsistent with the duties and character of a priesthood; and, accordingly, they have declined alike in dignity, in reputation, and in knowledge. Yet their influence as a body still remains unshaken; neither the violence of conquest, nor the shock of revolution, nor even the power of time itself, appears to have sensibly impaired their dominion over the minds of the other castes. The institutions to which they owe their ascendancy, and by which it will in all probability be maintained for ages yet to come, have struck their roots so deeply, and become so intimately identified with the genius, character, habits, sentiments, feelings, prejudices, and daily usages of the people, as to resist the operation of all those natural, moral, and political causes which bring about changes in other countries, and, amidst all the evils incident to convulsions and innovations, ultimately contribute to the general advancement. In India, society appears to have been arrested at a particular stage of its natural progress, and re-constituted so as never to exceed the limit which it had attained before its onward tendencies were paralyzed, and the characteristic of immutability firmly established. Hence it may be considered as forming what the schoolmen would probably have denominated a political nunc stans; as standing to other communities of men in nearly the same relation that eternity bears to time: and hence, also, the permanency of an influence which the possessors of it take no means to extend or improve, in the conviction that it can never be materially abridged.

The authenticity as well as the antiquity of the sacred books of the Brahmins has been alternately asserted and denied, with equal zeal and pertinacity. Without entering into this question, however, it may be satisfactory to show of what materials these writings really consist; for if they are utterly worthless and contemp-

Brahmins most indecent description, as provocatives to devotion; tible in themselves, as indeed seems to be the case, it Brahmins. matters but little to inquire whether they be genuine ' or spurious, of ancient or comparatively modern origin. And, on this subject, we prefer citing authorities to delivering any opinion of our own. "The sacred writings of the Brahmins," says an able writer in the Quarterly Review, "have been long mentioned with those phrases of solemn wonder, which would still have misled the public, if the translations and extracts of them which have successively appeared had not discovered their puerility and imposture. It is therefore important that the Sanscrit books, which have been held up as so sacred and so ancient, and which some of our learned Orientalists obviously prefer to the Jewish historian, should be given to Europe in the languages familiar to every one; that we may not be blinded by the erroneous admiration of credulous and misjudging enthusiasts, but be enabled to criticise fairly, and judge impartially for ourselves." (Vol. ii. p. 68.) Mr Mill, speaking of Sanscrit poetry generally, pronounces a judgment still stronger than that delivered by the Reviewer. "These fictions," says he, "are not only more extravagant and unnatural, less correspondent with the physical and moral laws of the universe, but are less ingenious, more monstrous, and have less of any thing that can engage the affection, awaken sympathy, or excite admiration, reverence, or terror, than the poems of any other, even the rudest people, with whom our knowledge of the globe has yet brought us acquainted. They are excessively prolix and insipid. They are often, through long passages, trifling and childish to a degree which those acquainted with only European poetry can hardly conceive. Of the style in which they are composed, it is far from too much to say, that all the vices which characterise the style of rude nations, and particularly those of Asia, they exhibit in perfection. Inflation, metaphors perpetual, and those the most violent and strained, often the most unnatural and ridiculous, obscurity, tautology, repetition, verbosity, confusion, incoherence, distinguish the Mahabharat and Ramayan.' (History of British India, vol. ii. p. 46.) The following passage, extracted from a most masterly article which appeared in the Edinburgh Review (vol. xv. p. 175), is, if possible, still more to our present purpose. "It may be said," the Reviewer observes, "that in a country of which the actual condition is so imperfectly known, investigation should first be directed to the existing state of society, which admits of being accurately ascertained, and may lead to practical conclusions highly beneficial to the community, before we attempt to explore the obscure paths of remote antiquity, by the feeble lights afforded by a few mutilated or suspicious documents. The Indian nations, it may be contended, have no claim to any extraordinary attention, either from the philosopher or the historian: their boasted civilization has rather been asserted than proved; neither their literature nor their arts indicate any considerable progress in the pursuits which refine and adorn mankind; and some of their customs betray a ferocity scarcely to be found amongst the most savage nations. But, even admitting that it would be desirable to trace the remote revolutions which this people have undergone, the little probability of attaining any deductions which may be relied on with confidence ought to induce us to relinquish so hopeless a task. The Puranas appear to be extravagant romances, which, however amusing as poetical compositions, can furnish no additions to authentic history, whatever portion of it they may be supposed incidentally to contain. When we find gods and heroes mingling in doubtful fight; events natural and supernatural succeeding each other indifferently; a fact probably historical, followed by another evidently allegorical; the only rational conclusion is to consider the whole of these poems

Brahmins as works of imagination, and to appreciate their merits by the rules applicable to similar compositions amongst other nations. But if such be the judgment we must pass on the Puranas, the Hindu compositions of a later date are not better entitled to attention, unless with respect to poetical excellence: and it probably may be affirmed that the Hindus cannot produce a single historical composition; whilst the Mahommedans of the same country have amply, and even ably, illustrated all the events subsequent to their entrance into Hindustan."

Such are the judgments which have been pronounced by some of the ablest writers of our time, respecting the sacred writings of the Brahmins, and the impossibility of deducing any sound or rational conclusions from these fanciful and extravagant compositions. But, on the other hand, it has been contended, with much plausibility and some degree of justice, that an indiscriminate accumulation of facts is no object with the philosopher, and only a subordinate one with the historian; that in proportion to the peculiarity and reputed antiquity of the religious and civil institutions subsisting amongst any people, it is natural to feel curiosity as to their origin; that the minute peculiarities which discriminate the nations of Europe scarcely produce any sensible modification of character, or exhibit to our observation any beings whose manner of thinking and acting is materially different from our own: that, in order accurately to appreciate the efficacy of religious dogmas and civil institutions in modifying the character of a people, our observation should be particularly directed to those nations which, in these respects, differ most widely from ourselves; that to this source may be traced much of the instruction as well as amusement derived from a perusal of the classic compositions of antiquity; that, from the same cause, the manners of savage tribes have attracted and deserved the attention of the philosopher, although these are in general extremely uniform, and little modified by any other circumstance than the greater or less facility of obtaining food; that, nevertheless, it is not amidst a people in such a stage of society that the influence of moral impressions can be accurately ascertained; that a nation must have advanced some steps in civilization, must have cultivated the arts, and been if, upon these grounds, the peculiarities of the Hindu institutions, opinions, and manners, deservedly render them the object of philosophic research, the gradations by which such a state of society was attained must be highly intesuch literary monuments as are still extant among them. Their sacred books, therefore, must ever possess a value, independent of all that may be said of their contents, or objected to the antiquity claimed for them. They embody evidence of the existence of peculiar modes of thinking, and forms of belief, as well as of the effects produced by peculiar institutions, civil and religious; and, as such, they can never cease to be regarded with interest, both by the philosopher and the historian.

Of ancient Brahminical science the principal remains are their astronomical tables and trigonometrical methods, both of which have given occasion to frequent and learned discussion in this and other countries of Europe. At present, however, we can only refer the reader to the works of Bailly, Playfair, and Delambre, in which he will find the subject treated with equal learning, ingenuity, and scientific precision, though in opposite views, and with confined to the construction and explanation of the almanack; and even this scanty amount of knowledge is the festivals the Brahmins exhibit the same species of idolatry,

portion of but few of their number. They have indeed fal- Brahmins. len from the proud eminence which was occupied by their order when the sages of Greece travelled into India to learn wisdom in that great storehouse of knowledge, and afterwards to carry it back to their own country, in order to plant there the first seeds of civilization. But there is one species of learning for which they have always evinced a singular aptitude and inclination; we mean metaphysical speculation, which possesses many attractions to men remarkable alike for the indolence of their habits and the extreme subtilty of their genius. In this department of research they had accordingly explored the whole cycle of systems, distinctions, classifications, refinements, and doubts, long before the western world had emerged from primeval barbarism; and in India the human mind had exhausted itself in endeavouring to detect the laws which regulate its own operations, when the philosophers of Greece were only beginning to enter within the precincts of metaphysical inquiry. Nor is it by any means certain that the latter are entitled to the credit they have received on the score of originality; that they did not borrow rather then invent; and that to the Gymnosophists of India belongs the honour of framing those systems which have been, perhaps too hastily, attributed to their disciples. It is even doubtful whether Aristotle himself did not derive both the materials and the arrangement of his system of logic from the same source. In a Mahommedan history, quoted by Sir William Jones, it is expressly mentioned that Callisthenes, having procured a regular treatise on logic, somewhere in the Punjab, transmitted it to Aristotle; and although this does not certainly prove that the Greek philosopher adopted as his own the system which had been sent him by his pupil, it at least warrants a conjecture that he might have done so; more especially as the syllogistic method was undoubtedly known in India long before his time, and as the fact must have been discovered by the numerous learned and accomplished men who accompanied Alexander's expedition. But be this as it may, one thing is pretty certain, that there is scarcely a hypothesis advanced by metaphysicians in ancient or modern times, which may not be found in some of the Brahminical writings. In these we meet with materialism, atomism, pantinged with science, before it becomes susceptible of that theism, Pyrrhonism, idealism, and every other fanciful vaindelible stamp which defies the efforts of time; and that riety of opinion which has yet been imagined or promulgated respecting God, the world, and the human soul. The Brahmins could boast of their Spinozas, their Berkeleys, and their Humes, long before Alexander dreamt of passing the Indus, and erecting a throne on the banks of the sacred resting, and can only be discovered through the medium of stream. That Pythagoras borrowed from them the greater part of his mystical philosophy, his notions respecting the properties of numbers as expressive of physical laws, his doctrine of the transmigration of souls, and the arguments by which he inculcated the unlawfulness of eating animal food, seems to admit of no doubt whatever; for all these things are of the very essence of Brahminism, and are to this hour taught and enforced by the sacred order in India.

Egypt and India, as we have already observed, are the only two countries in which the institution of castes has obtained in its most rigid form. This identity is of itself sufficiently remarkable; but there are other points of resemblance which we think even more striking. In ancient Egypt the cow was a principal object of religious adoration, and as such accounted peculiarly sacred; and we need scarcely add that, in India, the same superstition has prevailed to an equal, if not greater extent, ever since the introduction of the Brahminical religion. The Egyptians very different aims. As to the science of the modern worshipped Apis or the sacred bull, and the figure of this Brahmins, it seems, as we have already remarked, to be animal forms part of every hieroglyphical inscription, either as a symbol or a phonetical character. In some of their

Brahooick with rites and observances exactly similar to those anin the same sense, may be predicated of the Hindu mysuperstitions from India, or has India borrowed its mythology from Egypt, or have both drawn from a common source? Which is the original and which the copy, or are both merely copies from an original no longer extant? These are questions to which, in the present state of our knowledge, it is difficult, if not impossible, to give a satisfactory answer; although speculation has been busy on the subject, some contending in favour of Egypt, others in favour of India, and others, again, seeking a common source in that intermediate region, which formed as it were the cradle of the human race. We have no intention whatever to enter into these disputations, or to hazard conjectures respecting a subject in regard to which no safe or certain data have as yet been obtained. We may nevertheless be permitted to observe, that the question is chiefly one of pure chronology; that on this subject much still remains to be done before we can arrive at any well-founded conclusion respecting the comparative antiquity of these ancient nations; but that, in as far as we are at present able to see our way, the balance of probability appears to incline pretty decidedly in favour of the country of the Pharaohs.

venience of furling them. BRAIN. See Anatomy; Mental Diseases; Phreno-

LOGY; PHYSIOLOGY; and the Index.

BRAINERD, DAVID, one of the most zealous and successful of modern Christian missionaries, was born at Haddam, in the state of Connecticut in 1718, and died October 9.1747, in the house of his friend President Edwards. His heroic and self-denying labours among the American Indians, wore out in the course of a few years a naturally feeble constitution, but left behind them important fruits. The narrative of his mission is contained in his journal, published in 1746. His life, compiled chiefly from his own diary, was written by President Edwards, and has gone through many editions. Brainerd was a man of strong mental powers, extensive knowledge, and great sagacity; and as a preacher he was forcible and pathetic.

BRAINTREE, a market-town of Essex, in the hundred Braintree Mountains ciently practised in the country of the Pharaohs; and, of Hinckford, eleven miles N. by E. of Chelmsford. Did Egypt derive its tion of the Duke of Alva. Straw-plaiting has been introduced of late years. There is a free school in the town, besides several charities, distributed over fourteen different places. Pop. (1851) 2836.

BRAIT, among jewellers, denotes a rough diamond.

BRAKEL, JAN DE, a brave officer of the Dutch navy, born in 1618. He greatly distinguished himself on many occasions, but chiefly by his gallant struggle in 1672 against the combined fleets of Britain and France. He fell in an action against the French in 1690.

BRAKENBERG, REINTER, a Dutch painter, born at Haerlem in 1649, was a pupil of Mommers, and according to some accounts, of Bernard Schendel. His pictures display considerable skill and freedom in composition, but are bad in design, and often licentious in subject.

BRAMA, the Bream, a fish of the family of Squamopinnæ of the acanthopterygious order. The only known species is Ray's Bream, a native of the Mediterranean, but often caught on our coasts (Yarrell's British Fishes). See

CHITHYOLOGY, and ANGLING.

BRAMAH, Joseph, a practical engineer and machinist, was born at Stainborough, in Yorkshire, on the 13th of April 1749. His father rented a farm on the estate of Lord Strafford; and, being the eldest of five children, he was intended for the same employment. He exhibited at a very early age an unusual talent for the mechanical arts, and succeeded, when he was quite a boy, in making two violoncellos, which were found to be very tolerable instruments; as well as in cutting a single block of wood into a violin, chiefly by means of tools which were forged for him by a neighbouring smith, whom, at a subsequent period of his life, he induced to assist him in London as one of his principal workmen. Notwithstanding the ingenuity which he had thus displayed, his destination in life might have precluded its further cultivation, had he not, fortunately for himself and for the public, been incapacitated, when he was about sixteen, by an accidental lameness in his ancle, for the pursuit of agricultural labour. He was then apprenticed to a carpenter and joiner, who seems, however, to have contributed but little towards his improvement in mechanical knowledge.

When the term of his engagement had expired, he obtained employment for some time in the workshop of a cabinet-maker in London, and soon after established himself as a principal in that business. Another accidental confinement left his mind at liberty for a time to occupy itself with reflection and invention; and he employed his involuntary leisure in the improvement of some of the most humble, but not the least useful, of domestic conveniences. He obtained a patent for his inventions, and established a manufacture of these and other similar articles in Denmark Street, Soho, where he continued to simplify and improve the arrangement of the pumps and pipes subservient to his principal purpose. He procured in 1783 a patent for a water-cock, intended to allow the

Bramah. fluid a more uninterrupted passage through it than was as part of an apparatus for retaining, drawing, and clari-Bramah.

In 1784 Mr Bramah took out a patent for his improvement in locks, which certainly appear to be of very material importance. Their peculiar character depends on the arrangement of a number of levers or sliders, in such a manner as to preserve, when at rest, a uniform situation, and to be only pressed down by the key to certain unthe levers not having any stop to retain them in their required situation, except that which forms a part of the key. The construction is more particularly detailed in the specification of the patent (Repertory of Arts, vol. v. p. 217), as well as in the inventor's Dissertation on Locks, 8vo; and some additional modifications, allowing the key to be varied at pleasure, are described in a patent, dated in 1798. It is not easy to say why the application for an act of parliament to prolong the privilege proved unsuccessful, unless it was supposed that the inventor had been already sufficiently remunerated for the share of ingenuity which his contrivance exhibited; but the report, that one of these locks had been readily opened, before a committee of the House of Commons, by means of a common quill, was a gross misrepresentation of the fact; the quill having in reality been previously cut into the required shape from the true key. The experiment, in fact, only served to show the perfection of the workmanship, so little force being required to overcome the resistance when properly applied.

For different modifications of pumps and fire-engines Mr Bramah took out three successive patents, the two last being dated in 1790 and 1798. (Repertory, vols. ii. iii.) His "rotative principle" consists in making the part which acts immediately on the water in the form of a slider, sweeping round a cylindrical cavity, and kept in its place by means of an eccentric groove; a construction which was very possibly suggested by his own inventive mind, but which had been before described, in a form nearly similar, by Ramelli, Cavalleri, Amontons, Prince Rupert, and Dr Hooke. The third patent related chiefly to the attachment of a considerable reservoir of water to the fire-engine in a cylindrical form, and to the furnishing of it with wheels of its own, of a proper size and strength

to allow it to be conveniently worked.

There was somewhat more of originality in the idea of applying practically, to the purpose of a press, the well-known principle of the hydrostatic paradox, by which, as by a lever with arms capable of infinite variation, the smallest imaginable weight is made capable of holding in equilibrium a force incomparably greater. Mr Bramah's patent for the invention is dated in the year 1796 (Repertory, vol. vi. p. 289), and it has been one of the most successful of his numerous speculations. He added to it, in a subsequent patent, the contrivance of a "retainer," for keeping goods in a constant state of pressure for an unlimited time after their removal from the press. The paring the apparatus. apparatus has certainly a considerable advantage in the great steadiness with which the force can be applied, in ried into execution in a particular department, notwiththe facility with which it can be regulated, and the convenience with which it can be continued without alteration; and it has been extensively applied, both on a small and on a large scale, for copying writings, for pressing gunpowder, for proving cables and chains, for raising weights of various kinds, and for drawing piles, and pulling up trees by the roots.

A simple but a very convenient arrangement of little pumps and pipes has been very generally employed in public-houses under the name of the beer-machine: for this Mr Bramah took out a patent in 1797, describing it substitute for common printing, copperplate engraving,

practicable in the ordinary construction. He afterwards fying liquors (Repertory, vol. ix. p. 361). He prefaces removed to Piccadilly, and established the various branches his specification with some general observations on the of his manufactory in some extensive premises at Pimlico. right of an inventor to a property, both in the objects which he selects for his improvements, and in the means which he employs for the attainment of them; and demands of the public justice an ample security for both these rights, grounding this claim on his resolution to make a clear and unreserved disclosure of all his inventions. Besides the method of pumping up the liquors equal depths, which nothing but the key can ascertain; from the various casks through flexible pipes, without the necessity of entering the cellar, he describes a mode of converting every cask into a forcing pump, excluding the air, and raising the liquor to any part of the house, by a load on its head, which is to be converted into a piston. He mentions also a filtering machine, a vent peg, a method of making pipes, and a new form of stop-cocks.

In 1801 he obtained a patent for some improvements in the construction of steam-engines, particularly relating to the boilers; and in 1802, one for a very elaborate and accurate machine for producing smooth and parallel surfaces on wood and other materials. The tools of different kinds employed in this machine, such as gouges, spokeshaves, and planes, are carried with a considerable velocity by a rotatory motion, and come successively in contact with the wood, which is placed on a movable carriage gradually advancing. The centre or gudgeon of the axis or shaft, instead of a common step, is supported by a barrel of oil, to which it is fitted by a collar; and this arrangement not only diminishes the friction very considerably, but allows the height of the shaft also to be very easily and accurately regulated by means of a small forcing pump. The inventor thinks this liquid support likely to be as permanent as it is advantageous; but it may be apprehended, that the constant friction of such a collar would cause it to require frequent repairs, in order to prevent the escape of the oil so powerfully compressed. The machine has been erected on a large scale in the arsenal at Woolwich, and is employed with perfect suc-The specification includes the description of a mode of turning spherical surfaces, either convex or concave, by the simple contrivance of a tool, movable on an axis precisely perpendicular to that of the lathe; and of cutting out concentric shells, by fixing, in the same manner, a curved tool, nearly of the same form as that which is employed by the common turners for making wooden bowls.

An improvement in the processes for making paper, with the assistance of new machinery, in large sheets, was secured to the inventor by a patent in 1805 (Repertory, second series, vol. viii. p. 1). The description is accompanied by that of a mode of drying the paper on sliding frames, hung on lines like sashes, and of keeping it in a state of compression by retainers adapted to the hydrostatic press; but Mr Bramah had not leisure to introduce these arrangements into actual practice, although he had been at a considerable expense in pre-

His next invention was, however, very effectually carstanding its unpromising appearance, as generally stated in the specification of the patent, which he obtained in 1806 (Repertory, second series, vol. x. p. 329). He proposes to facilitate the process of printing by means of a roller, composed of a number of circular plates, closely fitted together, and turning on the same axis, each bearing twenty-six letters, with figures, spaces, and various marks, either engraved or projecting, and capable of being shifted at pleasure, so as to express any single line by a proper combination of the plates. This is described as a

Bramah and calico printing; and the ink is intended to be supplied by a trough fixed above, and in contact with the cylinder. Now it is obvious that such a machine would be insufferably tedious and inconvenient for every purpose of common printing, which it would be scarcely possible to perform by its means; but when we discover that the inventor had probably in view the apparatus which he constructed the next year for the Bank of England, for numbering and dating their notes, we shall be aware that the means were admirably adapted to the end; a single line only being here wanted at once, in which a single figure was to be changed at each step, and that in a regular order. In fact, during the immense temporary circulation of one and two pound notes, the Bank has been able, by this machinery, under the management of about twenty clerks, to perform the labour of 120, who were before required for the purpose.

Mr Bramah procured a patent in 1809 for a mode of making and holding pens for writing, calculated to save the substance of the quill, by cutting a number of pens out of it, instead of a single one; and those who are not in the habit of making their own pens may often find a convenience in the portable form in which this and other similar "pterophori" are arranged. In 1812 he brought forward his patent for the construction of main pipes, to be carried through the principal streets of a metropolis, of sufficient thickness to withstand a great force, to which the water within them is intended to be subjected, by proper pumps, furnished with air-vessels; so that the water may not only be ready for the immediate extinction of fires, without the necessity of bringing an engine to the spot, but may also furnish a convenient moving power for various mechanical purposes, such as raising weights, by means of tubes sliding out of each other, like those of a telescope. He observes that he has frequently had occasion to employ a hydrostatic pressure, in many of his operations, equivalent to that of a column of water 20,000 feet high, which is about four tons for every square inch. He also asserts that he can form 500 tubes, each five feet long, capable of sliding within each other, and of being extended, in a few seconds, by the pressure of air forced into them, to a length of 2500 feet; and, with a power of this kind, he seems to have imagined that he could raise wrecks, and regulate the descent of weights of various descriptions.

His improvements in wheel-carriages, for which he obtained a patent in 1814, consisted in fixing each wheel to a separate movable axis, having its bearings at two distinct points of its length, but loosely inclosed between these points in a cylinder filled with oil; and, in some cases, he proposes to fix the opposite wheels to the same axis, though with a power of turning very stiffly round it, in order to lessen the lateral motion of the shafts in very rough roads. He also suggests the use of pneumatic springs, formed by pistons, sliding in cylinders, as a substitute for common springs of metal.

The purpose of Mr Bramah's last patent was the prevention of the dry rot, by laying on the timber meant to be preserved from it, a thin coat of Parker's Roman cement, much diluted with water; but he does not appear to have pursued this experiment, having transferred his right in the invention to other hands.

In addition to the seventeen patents which have been mentioned, he took out two or three others of less importance, at different times; besides a variety of contrivances, which he did not think it necessary to appropriate to himself by a legal privilege. Mr Nicholson has mentioned a double plunger for a forcing pump, as described to him by Mr Bramah (Nich. Jour. vol. vii. p. 50), which,

paratus the effect of a much smaller. Mr Bramah had erected, in the latter years of his life, some large machines at the Thames bank for sawing stones and timber; Bramante. he had begun to devise some improvements in bridges and in locks for canals; and he had at one time been actually employed in the execution of some water-works belonging to the department of the civil engineer, which he completed with ability and with success. His great and various exertions appear in some measure to have exhausted the strength of his constitution; and his last illness was immediately occasioned by a severe cold, taken in the prosecution of his experiments on the tearing up of trees, made in Holt Forest. He died in his sixty-sixth year, on the 9th of December 1814.

Mr Bramah was a sincere believer in the doctrines of the Christian religion; and, notwithstanding his diversified avocations, he left several manuscript essays on religious subjects. In his moral character he was cheerful, benevolent, and affectionate; in his habits he was neat and methodical; and he knew well how to temper liberality with economy. He often kept his workmen employed more for their sake than his own, when the stagnation of trade deprived him of the means of disposing of the products of their labour. It is surely on the characters of such individuals that the wealth and prosperity of the British empire most essentially depend; an inventive imagination controlled by a sound judgment, an incessant activity of mind and body, a head that can direct, and a heart that can feel, are the genuine sources of that practical superiority which is well known to distinguish the productions of our national industry. (Life of Mr Bramah, by Dr Brown, in the New Monthly Magazine for April 1815.)

Bramah's Press. See Hydrodynamics.

BRAMANTE, DONATO-LAZZARI, a celebrated architect, whose family was of Castel Durante, now Urbania, in the state of Urbino, where he is generally said to have been born, though others assert that he was a native of Monte Asdrualdo, a villa four miles from Urbino. Collucce assigns 1450 as the year of his birth, but Vasari states it as 1444. Cardinal Oliviero Caraffa brought him to Rome, and introduced him to Alexander VI., for whom he designed and erected the Chancery, a somewhat heavy pile, yet grand from its spacious tiers of arched galleries around a court, sustained by granite columns. Julius II., with whom he became a favourite, first employed him to connect into one vast whole the Belvedere with the older portions of the pontifical palace, which he accomplished so as to produce an imposing mass out of very heterogeneous materials. When the imperious and impatient pontiff determined in 1513 to rebuild St Peter's, he employed Bramante on the design; and such was Bramante's zeal and industry, that not only was the design completed, but the architect had erected the four great piers and their connecting arches before his death, which took place in the following year. The designs of Bramante were lost sight of by those who succeeded him in this vast work; and notwithstanding the boldness of the majestic dome of Michael Angelo, many Italians have regretted that the designs of Bramante were departed from, more especially in the present bald and tasteless western façade, which has nothing but its magnitude to deserve commendation. One of Bramante's best designs now remaining is the fine oratory in the cloister of San Pietro Montorio, a little circular temple with a colonnade of great elegance on three circular gradini.

Bramante was not merely an architect and a painter, but also a poet, as appears from the volume of his works published at Milan in 1756. He was the uncle of Raphael, whom in the form he has delineated, is certainly possessed of he instructed in architecture, and introduced to the notice no particular advantage, producing only with a large ap- of Julius II. The painter has gratefully commemorated his

Bran.

Braman- master by placing him in his School of Athens. Bramante number of the Bulletin de la Societé Industrielle de Mul- Branchide died at Rome in 1514.

BRAMANTINO, the name of several Milanese artists, of whom Bartolomeo Bramantino, or more properly Suardi, was the most eminent. He flourished about 1450, and distinguished himself as an architect and a painter. From him Lazzari Bramante is said to have derived much instruction relative to his art. He erected many churches in the Milanese territory, among which may be mentioned that of St Satyrus. (See Lanzi.)

BRAMBANAN, a village of Java, near its eastern extremity, in the region of Mataram, eight miles from Saracarta. It is noted for the remains of Hindu images, temples, and inscriptions, which are spread over an extent of ten miles. The most remarkable of those ruins are known under the name of the Thousand Temples, which constitute a square group of buildings, each side measuring 250 paces. One large temple stood in the centre of the square, which was surrounded at equal distances by three rows of smaller ones, the rows being but a few feet distant from each other. At each of the four cardinal points, where there appear to have been gates, were two gigantic statues, each of them with a mace in its hand, and a snake twisted round its body. The inside walls of the large temple were adorned with figures of the conch shell, of water-vases, and of the sacred lotus, all denoting a Hindu origin. There is no reliable evidence to show at what period those immense buildings were constructed. A Javanese manuscript asserts that it was in the Javanese year 1188, which corresponds to the year of the Christian era 1261.

BRAMHALL, John, D.D., archbishop of Armagh, was born of an ancient family at Pontefract in Yorkshire, A.D. 1593. He was invited to Ireland by the lord deputy Wentworth, and soon afterwards obtained the archdeaconry of Meath, the best in that kingdom. In 1634 he was made bishop of Londonderry. He rendered great service to the church of Ireland by procuring the passing of several acts for abolishing fee-farms and recovering impropriations, by which, as well as by other means, he regained to the church in the space of four years about L.40,000 a-year. In the Convocation he was instrumental in persuading the church of Ireland to adopt the Thirty-nine Articles; and he exerted himself, though ineffectually, to get the English canons established in Ireland. Articles of treason were exhibited against him in the Irish parliament; and at the treaty of Uxbridge in 1644, the English parliament made it a preliminary article, that Bishop Bramhall, with Archbishop Laud, and others, should be excepted from the general pardon. Upon this he went abroad; but on the Restoration, he was appointed archbishop of Armagh, primate and metropolitan of Ireland, and was chosen speaker of the House of Lords. He died in 1663. His works were published in 1677, in folio.

BRAMPTON, a town of England, in the county of Cumberland, Eskdale ward, 10 miles N.E. of Carlisle, erroneously supposed by Camden to be the Bremetenacum of the Romans, lies in a narrow valley at the confluence of the Irthing and Gelt. The houses are for the most part old and meanly built. It contains four dissenting chapels, a town-hall, built by the Earl of Carlisle in 1817, a grammarschool, and a market-house, in which very large quantities of corn are annually sold. Gingham and check-making are the only manufactures of the town. Pop. (1851) 3074.

BRAN, the outer skins or husks of ground wheat, rye, or other farinaceous grain, separated by the boulter from the flour. Wheat bran is employed in the manufacture of starch, and by dyers in making the "sour water" used in preparing the dyes. By the process of boiling in branwater, calico-printers remove colour from those parts of maddered goods which are not mordanted. Some valuable observations on this subject will be found in the ninth

hausen. See Dyeing.

BRANCHIDÆ, the hereditary priests of the temple of Apollo, at Didyma, in Ionia. They delivered up the treasures of the temple to Darius or Xerxes; and then, fearing the vengeance of the Greeks, they fled to Bactria or Sogdiana, upon the frontiers of Persia, where they built a city called by their own name. The punishment of their crime, however, fell upon their descendants, who were massacred by the army of Alexander the Great, and their city was destroyed.

BRAND SUNDAY, Dimanche des Brandons, in French ecclesiastical writers, denotes the first Sunday in Lent, which is thus called on account of an ancient practice in the Lyonnois, where the peasants walked by night about their orchards and gardens with lighted torches or firebrands in their hands; visiting every tree, addressing each one in turn, and threatening that if it did not bear well the ensuing season it should be cut down and burnt. This custom prevailed in many places till the middle of the seventeenth century. It was evidently a relic of paganism, akin to the ancient Lupercalia, or shepherd-festival, which was celebrated on the 15th of February, Februarius, i. e. the month of purification.

BRANDENBURG, one of the larger provinces into which the kingdom of Prussia is divided, and the division from which that powerful monarchy originally sprung. See Prussia. It is situated between Lat. 57. 0. and 53. 34. N. and Long. 11. 25. and 16. 10. E., and is bounded on the north by Mecklenburg and Pomerania, east by West Prussia and Posen, south by Silesia and the kingdom of Saxony, and on the west by the province of Saxony and Hanover. It has an area of 15,538 square miles, and is divided into the two governments of Potsdam and Frankfort, having 30 circles, 138 cities, 27 market-towns, and 3073 villages. The entire province is nearly a sandy plain, but interspersed with a few fertile spots; and a considerable portion of it is covered with woods. It is generally well watered by streams, most of which empty themselves into the Elbe or the Oder. The chief agricultural product is rye, with some wheat, barley, oats, and buckwheat. Fruit of all kinds is abundant, as well as culinary vegetables; and considerable quantities of hemp, flax, and hops are raised. The climate is cold and raw in winter, and excessively hot in summer. The manufactures are chiefly confined to Berlin and the other cities; but the rural inhabitants are employed in spinning or weaving, and produce much linen cloth. In 1849 it had 2,129,022 inhabitants, of whom 1,069,043 were males, and 1,059,979 females; 968,717 lived in towns and 1,160,305 in the country; 2,076,608 Protestants, 32,514 Catholics, 19,761 Jews, 23 Mennonites, 115 belonging to the Greek church, and 1 Mohammedan. There were 2880 primary schools with 289,869 scholars, 79 middle schools for boys, with 17,465 scholars, 224 similar institutions for girls, with 20,795 scholars, 34 higher schools and gymnasia with 8924 scholars, and 4 normal schools with 276 scholars, being in all 337,329 scholars, or nearly onesixth of the entire population.

Brandenburg, a town of Prussia, capital of the circle of West Havelland, in the government of Potsdam, and province of Brandenburg. It is situated on the river Havel, and also on the Magdeburg and Berlin railway, 37 miles W.S.W. of Berlin. It was founded about the seventh century by some Slavonian tribes, who were afterwards driven out by Albert the Bear, and Brandenburg became the capital of the mark of the same name. The town is inclosed by walls, and is divided into three parts by the river, the old town on the right and the new town on the left bank, while on an island between them is the "cathedral town," also called from its position "Venice." The cathedral, an ancient structure of the fourteenth century, the old church

Brandy.

Brandeum of St Katharine, erected in 1410, and the council-house, deserve notice for their antiquity and works of art. There are also a castle, gymnasium, riding academy, public library, theatre, and several hospitals. In the market-place stands the Rolandsaule, a column 18 feet in height, hewn out of a single block of stone. The town has a very considerable trade, and manufactures of woollens, linens, liosiery, and paper, with breweries, tanneries, and boat-building. Pop. (1849) 18,309.

BRANDEUM, in ecclesiastical writers, a linen cloth or veil put over the tombs of the apostles Peter and Paul, and left there some time that it might acquire a degree of sanctity, entitling it to be worshipped as a relic; and as such it was frequently sent by the pope as a present to some prince. It was otherwise called sanctuarium, sudarium, orarium, and velum. The use of brandéa was introduced as a means of diffusing the virtues and influences of relics, their translation in early times being prohibited.

BRANDING, a punishment inflicted by impressing a mark with a hot iron on the face or the hand.

BRANDON, a town in England, in the county of Suffolk, hundred of Lackford, on the Little Ouse or Brandon river, 88 miles from London by rail. In the neighbourhood of the town are numerous flint-quarries, which during the last war supplied the army with gun-flints. Its trade in this article has been wholly destroyed since the introduction of the percussion cap. Brandon anciently gave its name to the Dukes of Suffolk, and the title of baron to the Earls of Macclesfield. It now gives his English title to the Duke of Hamilton. Pop. (1851) 2022.

BRANDRITH, an iron trevet or stand for supporting a vessel over the fire.

Brandrith, or Brandrette, among builders, denotes a fence or rail around the mouth of a well.

BRANDT, an alchemist of Hamburg, in the end of the seventeenth century, who in his researches after the "philosopher's stone" is said to have accidentally discovered phosphorus. (F. Hoefer, Hist. de la Chimie, ii. 201.) He concealed the process; but it was discovered soon after by Kunckel, and hence it has been called Kunckel's phosphorus.

Brandt, Gerard, a learned divine of the Reformed religion, was born at Amsterdam in 1626, and was successively minister in several places of the Netherlands. His works were numerous and popular, especially a History of the Reformation in the Low Countries, Amsterdam, 1671-74, in 4 vols. 4to, which was translated into English, and published at London in 1719, 8vo; The Life of Admiral de Ruyter; An Account of the Trial of Barneveld, Hoogerbeets, and Grotius, in 1618, Rotterdam 1619, 4to; and Oratio Funebris Cornelii Hooftii, Satrapæ Mudani, Amsterdam 1648; all, except the last, in the Flemish language. Brandt died at Rotterdam in 1685.

Brandt, Sebastian, a man of letters of the fifteenth century, author of a rare treatise entitled Stultifera Navis, illustrated with curious woodcuts, printed in 1490. Several authors have erroneously represented him as the artist of the engravings, but they seem to be the work of Jan Bergmann.

BRANDY, a spirituous or alcoholic liquor, extracted from wine by distillation. When pure it is perfectly colourless, but it soon acquires a yellow tinge from the cask. The deep colour of common brandy is generally given by the addition of burnt sugar, caramel. The wine-brandy of France is esteemed the best in Europe. The chief brandies for foreign trade, and those accounted best, are those of Cognac, Bordeaux, Rochelle, Charenton, the Isle of Rhé, Orléans, the county of Blasois, Poictou, Touraine, Anjou, Nantes, Burgundy, and Champagne. The best brandy is distilled from wine of any kind, but is generally made from wine that has become too acid for the market, or what is technically called pricked wine. An inferior sort is made from the husks of the pressed grapes; but this contains an acrid oil which exists in the skin of the fruit and injures its fla-

vour. (Annales de Chimie, tom. 64.) The flavour of brandy is said to be sometimes imitated by adding to grain spirit a small proportion of nitrous ether. (See DISTILLATION.)

The import of brandy to the United Kingdom in 1853 was 1,870,567 gallons. The amount of duty paid was

L.1,402,932, the rate being 15s. per gallon.

BRANK, or scolding-bridle, an instrument formerly used in Scotland, and some parts of England, for correcting scolding women. It consisted of a head piece, which opened and inclosed the head of the shrew, and was furnished with a sharp iron, which entered the mouth and restrained the tongue. Thus harnessed, the offender was led in triumph through the streets. Dr Plott, in his History of Staffordshire, has given a description and figure of this instrument.

BRANTOME, PIERRE DE BOURDEILLES, LORD ABBOT OF, a French courtier of the reign of Charles IX., and his mother Catherine de' Medici, was born about 1527, and died at his château of Richemont in 1614. He is best known by his posthumous *Mémoires*, which first appeared in 1666; but the most complete edition is that of 1740, in 15 duodecimo volumes. They contain a very lively account of the manners of that age, and an unblushing chronicle of the profligacy of the writer, and of the courts and times in which he lived.

BRASIDAS, son of Tellis, a celebrated Lacedæmonian general, in the early part of the Peloponnesian war. He defeated the Athenians by land and sea, took many places, and rendered his native country formidable to all the neighbouring states. He repulsed the Athenians in their attempted surprise of Amphipolis, but died of the wounds he received in that battle, B.C. 422. See ATTICA.

In honour of him an annual festival, called Brasideia, was celebrated at Sparta. None but natives were permitted to attend; and whoever absented himself was fined. Brasideia were also celebrated at Amphipolis.

BRASS, an alloy of copper and zinc. This name, however, has not been exclusively applied to the alloy of these metals; for the gun-metal, which has been also called brass, is an alloy of copper with tin. The same alloy, with more tin, is used in machinery, and is preferred to the alloy of

copper and zinc, on account of its greater hardness.

It appears from the analysis of the brass of the ancients Different that it was an alloy of copper and tin. A small portion of kinds. tin gives to copper great hardness, and renders it capable of bearing much greater resistance. A larger portion of tin gives increased hardness, but is less fitted to bear a straining resistance, on account of its brittleness. Its elasticity is very great, which fits it for bells. In this state it is called bell-metal; and with a still greater proportion of tin it forms an alloy employed for the mirrors of reflecting telescopes. The alloy of copper with tin is easily distinguished from that with zinc, from the agreeable colour of the latter, which varies with the proportions of the metals. Pinchbeck has the least proportion of zinc. Common brass has more zinc, and the gold-coloured alloy called prince's metal contains a still greater proportion of zinc. An alloy of copper with a very large proportion of zinc is used for the common white metal buttons.

The various alloys of copper with tin and zinc forming Proportion the different kinds of brass, are to be considered as chemical of alloys. compounds, and, of course, governed by the same laws of definite proportions which obtain in the more conspicuous compounds. On these principles, which cannot be doubted, we have an unerring rule for uniting these and other metals in the best proportions, the weights of their atoms being previously known.

The weight of the atom of copper being 8, tin 7.35, and zinc 4, the following tables exhibit the proportions of the various alloys, expressed in atoms, and their proportions by weight, the third column pointing out the colour and character of the resulting compound. C, Z, and T are to represent the atoms of the metals respectively.

Brass.

Brank

Brass.

Atoms.	Proportions by Weight.	Character and Colour of the Compounds.
C+Z	2 to 1	The best proportions for common brass.
C+2Z	1 to 1	The alloy called prince's metal, of a beautiful gold colour.
C+3Z	2 to 3	Of a paler yellow, very little malle-
C+4Z	1 to 2	Still lighter in colour, and not mal- leable.
C+5Z	2 to 5	Yellowish-white, and brittle.
0+6 Z	1 to 3	Very brittle, nearly white.
2 C+Z	4 to 1	A very malleable brass, used in watch- work.
3 C + Z	6 to 1	An alloy much harder than copper, and inclining to its colour.

COMPOUNDS OF TIN WITH COPPER.

Atoms.	Proportions by Weight.	Character and Colour of the Compounds.
T+C	11 to 12	A very brittle and rather white alloy.
2T+C	11 to 6	Still more brittle and more white.
3T+C	11 to 4	Very white, used for speculums.
4 T + C	11 to 3	Coarse-grained, and too brittle for any purpose.
T+2C	11 to 24	A yellowish alloy, very hard and so- norous.
T+3C	11 to 36	Bell-metal.
T+40	11 to 48	A very hard alloy, used for some culi- nary vessels.
T+5C	11 to 60	Softer, but not malleable.
T+6C	11 to 72	Still increased in softness, and of a yellower colour.
T+70	11 to 84	Used for some purposes in machinery.
T+8C	11 to 96	An alloy used for cannon.
T+9C	11 to 108	More common for cannon and ma- chinery, and used for bronze sta- tues.
